FOURTEENTH EDITION	1930
FIFTEENTH EDITION	1936

LIST OF CONTRIBUTORS

- General Medicine.** E. P. POULTON, M.A., D.M. Oxon., F.R.C.P. Lond., Physician to Guy's Hospital, Consulting Physician to the London County Council, correspondant (Hon. Causa) de la Société de Thérapeutique de Paris, formerly Clinical Examiner in Medicine, Oxford University, Examiner in Medicine for the Conjoint Board, and Associate Examiner in Medicine, University of London.
- Diseases of the Nervous System.** C. P. SYMONDS, M.A., D.M. Oxon., F.R.C.P. Lond., Physician in Charge of the Neurological Department, Guy's Hospital, Physician to Outpatients at the National Hospital for Nervous Diseases, Queen Square, Consulting Neurologist to the Royal Air Force, Neurologist to the Central London Throat, Nose and Ear Hospital.
- Diseases of the Skin (Dermatoses).** H. W. BARBER, M.A., M.B. Camb., F.R.C.P. Lond., Physician in Charge of Skin Department, Guy's Hospital, Corresponding Member of the French, American and Vienna Dermatological Societies.
- Mental Diseases.** R. D. GILLESPIE, M.D. Glas., F.R.C.P. Lond., D.P.M. Lond., Physician and Lecturer for Psychological Medicine, Guy's Hospital, Examiner in Psychological Medicine, Royal College of Physicians and University of London, Corresponding Member of the American Psychiatric Associations.
- Diseases of the Tropics.** N. HAMILTON FAIRLEY, O.B.E., M.D. D.Sc. Melb., F.R.C.P. Lond., Assistant Physician and Director of Pathology, Hospital for Tropical Diseases, Lecturer in Clinical Medicine and Applied Pathology, London School of Hygiene and Tropical Medicine, Lecturer in Tropical Medicine, Westminster Hospital Medical School, Hon. Member of the American Society of Tropical Medicine, Corresponding Member of the Belgian Society of Tropical Medicine.
- Diseases of the Nose, Throat and Ear.** W. M. MOLLISON, C.B.E., M.Ch. Camb., F.R.C.S., Eng., Surgeon to the Ear and Throat Department, Guy's Hospital.

PREFACE TO THE FIFTEENTH EDITION

It is six years since the last edition of Taylor's Medicine was published and during this time there has been steady progress throughout the range of medicine. In the present edition Dr. Symonds, Dr. Barber and Dr. Gillespie have again been responsible for their respective sections of the book. The biggest change is in the section on Diseases of the Tropics, which has been almost entirely rewritten by Dr. N. Hamilton Fairley, who kindly consented to join us. It has been placed at the end of the book and, as it is as complete as is compatible with the number of pages that can be allowed in a text-book of general medicine, the subject appears as an organic whole, so that this section may be looked upon as an addendum to the rest of the book. Of course some overlapping is unavoidable; the diseases in this country due to worms are of more importance in the tropics and the variety of worms met with there is so large that this part of medicine is bound to be described among the tropical diseases. Attention may be drawn to articles on bites and stings, including snake bite, and to a section on tropical skin diseases.

The next important alteration is that the diseases of the larynx and tonsils, which have hitherto been described in different parts of the book, are now grouped together in a new section on Diseases of the Nose, Throat and Ear (from the medical aspect), which includes short articles on sinusitis and on the ear. Mr. W. M. Mollison has very kindly co-operated by revising and adding to this part of the subject.

Infectious Diseases have now been arranged on an aetiological basis beginning with those due to ultra-filterable viruses, then those due to bacteria, fungi, spirochaetes, protozoa, helminths and other metazoa. This order applies not only to the Infectious Diseases, but to Infections of the Skin and Tropical Diseases. Throughout this book the lettering of the headings has been simplified. In order to save space it has been considered desirable in the case of those rare diseases which are dealt with in quite a short paragraph, not to use headings of the same importance as for the common diseases, a description of which often occupies many pages. Consequently while for these latter diseases the headings are in capitals as hitherto and stand out in the middle of the page, for the former black italics are used and these are placed at the side of the page so that the continuity of the text is not broken. This has been pointed out, as otherwise these small black italic headings might be regarded as sub-headings of the more important diseases; but this is not the case.

The articles on the following subjects are new or have been considerably altered or added to; in the introduction, diet in infancy, dosage, remedial exercises, climate and natural waters; among the infectious diseases, variola minor, acute poliomyelitis, glandular fever, influenza, scarlet fever, tuberculosis in childhood, syphilis and poisoning by arsenobenzol, sporotrichosis and other uncommon mycotic diseases; among the respiratory disorders, dry bronchiectasis, pulmonary oedema, pneumonia, including the typing of pneumococci and treatment with serum and the oxygen tent, pulmonary abscess, bronchoscopy, anthracosis, silicosis, asbestosis, epituberculosis, the Mantoux test, and empyema; among the circulatory diseases, the size of the heart, the new alkaloids of digitalis, cardiac compensation and its failure, rheumatic fever, the prognosis of heart

disease, chronic constrictive pericarditis, prognosis of aortic aneurysm ; among the alimentary diseases, congenital pyloric stenosis, diarrhoea in infants, coeliac disease, liver function, fatty liver ; among the blood diseases, the Arneth count as simplified by Schilling, an hæmopoietic anæmias of adults and children, simple achlorhydric anæmia, pernicious anæmia, agranulocytosis, hæmolytic anæmias, Lederer's anæmia, purpura, hæmophilia, acidosis and alkalosis, Hodgkin's disease and rare diseases of the spleen, including Gaucher's and other diseases ; among the diseases of metabolism and internal secretion, basal metabolism, diet tables arranged on a new plan (to be published in full in a special monograph), hypoglycæmia, the parathyroids, the pituitary, including Cushing's syndrome, the suprarenals, the gonads and obesity ; among the diseases of the urinary organs, new methods of examination and of testing renal function, reaction of the urine, hydronephrosis.

The rheumatic diseases have now been brought together and new matter added, especially in relation to morbid anatomy and to spondylitis. The articles on beri-beri, rickets, renal dwarfism and poisoning by means of carbon monoxide have been altered. In the diseases of the nervous system the anatomical parts, which were previously scattered through the section with consequent overlapping, have now been brought together as an introduction, entitled "Applied Anatomy and Physiology" ; cerebral tumour has been rewritten. Among the mental diseases Dr. Gillespie is now responsible for the psychoneuroses, while there is a new article on psychological principles. Among the skin diseases there may be mentioned new articles on eczematoid streptococcal eruption of the scalp, erythema annulare centrifugum, granuloma annulare, pustular psoriasis, parapsoriasis, keratosis pilaris atrophicans, acanthosis nigricans, while alopecia has been reclassified. This list provides a conspectus of the chief advances of medicine in the period ; but there are of course many other smaller alterations and additions throughout the book and no trouble has been spared in attempting the task of keeping the book up to date. There are sixty-nine more pages. Certain articles like typhus and sprue have been transferred to the tropical section so that it is difficult to compare the lengths of the various sections in the two editions. Broadly speaking, the length of the sections on "Internal Medicine" and mental diseases remains the same as before ; the section on nervous diseases is ten pages shorter. The section on skin diseases is twenty-one pages longer, while the tropical section has been about doubled.

A number of the older plates have been replaced and the total number is now seventy-one as against sixty-four previously. The text-figures have been increased to 104.

It is my pleasant duty to thank many friends for help in different parts of the book. Professor R. T. Leiper has kindly read through the section on helminths and made suggestions. I should like to thank Dr. A. C. Hampson, for help in the children's diseases, Mr. V. E. Lloyd, for looking through the article on syphilis, Miss Angove, Sister in charge of the Massage Department of Guy's Hospital, and Mr. J. Rivers, who has again made the Index and helped in numerous ways.

E. P. POULTON

PREFACE TO THE TWELFTH EDITION

SIR FREDERICK TAYLOR'S "Practice of Medicine" has for thirty years held one of the foremost places as a text-book for students and practitioners, and it remains a splendid monument to the industry and knowledge of its author. To one whose lot it is to carry on the work there might well come a feeling of trepidation at the thought of following in the footsteps of such a leader.

Nevertheless, it was not a task that could be avoided, and in undertaking it my first thought was to try and find out what special features the book possessed that made it appeal to such a wide circle of readers. The completeness of the book seemed the most important—the fact that in a single volume the whole of medicine was represented, including such a speciality as Diseases of the Skin, a subject which is often omitted from text-books on medicine. Again, the book contained a detailed account of the method of examining the various systems of the body, so that it can be truly said that a student who read this book required no other during his course of study in the medical wards and out-patient department. It was evident that the main scope of the book must remain unchanged; but this very fact created a difficulty, because the range of medicine has increased so much of late that it is almost beyond the powers of a single individual to cover the whole ground himself. Sir Frederick Taylor and Sir William Osler will perhaps have been the last to have made the attempt. At the same time a text-book is apt to lose in continuity if there are too many writers, and so it was decided that, while I must myself revise the greater part of the work, two other authors should be asked to take in hand the sections dealing with the two definite specialities in medicine.

CONTENTS

PAGE

INTRODUCTION 1

INFECTIOUS DISEASES 10—119

Nature of infection, 10; immunity, 13; anaphylaxis, 15; pyrexia, 17; **diseases due to ultra-filterable viruses or of unknown origin**, measles, 24; rubella, 27; small-pox, 28; vaccination, 33; chicken-pox, 34; mumps, 36; influenza, 37; acute poliomyelitis, 40; psittacosis, 45; foot and mouth disease, 45; glandular fever, 45; **rickettsia**, trench fever, 46; **bacteria**, streptococcal infections, 47; scarlet fever, 48; septicæmia, 53; erysipelas, 54; staphylococcal infections, 56; pneumococcal infections, 56; gonococcal infections, 57; cerebro-spinal fever, 59; diphtheria, 63; whooping-cough, 69; typhoid fever, 71; tuberculosis, 83; paratyphoid fevers, 84; glanders, 91; anthrax, 92; tetanus, 94; gas gangrene, 98; **mycoses**, actinomycosis, 99; sporotrichosis, 101; blastomycosis, 102; torulosis, aspergillosis, 103; **spirochaeta**, syphilis, 104; congenital syphilis, 114; poisoning by arseno-benzol, 117.

DISEASES OF THE ORGANS OF RESPIRATION 120—194

Examination of the chest, 120; tracheitis and specific infections, 127; new growths, obstruction, 128; bronchitis, 130; bronchiectasis, 135; hay fever and asthma, the allergic state, 138; obstruction, 144; emphysema of the lungs, 145; collapse, 148; œdema, 149; pneumonia, 150; Friedländer pneumonia, broncho-pneumonia, 157; abscess, 159; fibroid lung, 160; gangrene, 162; pulmonary tuberculosis, 163; syphilis, poisoning by irritant gases, 176; pulmonary embolism and thrombosis, 177; intra-thoracic neoplasms, 179; pleurisy and empyema, 182; hydrothorax, hæmothorax, chylothorax, 189; pneumothorax, 190; diaphragmatic hernia, 192; mediastinitis, 193.

DISEASES OF THE NOSE, THROAT AND EAR (*from the medical aspect*) 195—215

Coryza, 195; chronic rhinitis, 197; sinusitis, 197; epistaxis, 197; tonsillitis, 198; Vincent's angina, 201; pharyngeal tonsils, 201; lingual tonsils, 202; chronic pharyngitis, 202; retropharyngeal abscess, 202; laryngitis, 203; tubercle, 205; syphilis, 206; tumours, foreign bodies, 207; paralysis of laryngeal muscles, 208; spasm of the glottis, 211; congenital laryngeal stridor, anaesthesia, 212; the ear, 213; otitis media, 214.

DISEASES OF THE ORGANS OF CIRCULATION 216—317

Examination of the heart, 216; capacity for effort, 223; X-rays, 224; radial pulse, 226; venous pulse, 229; **abnormalities of cardiac action**, 230; sinus irregularity, 232; heart-block and Adams-Stokes syndrome, 232; premature beats, 235; frequent action, 238; paroxysmal tachycardia, 239; auricular flutter, 241; auricular fibrillation, 242; pulsus alternans, infrequent action, 247; ventricular fibrillation, **diseases of the heart**, compensation, 248; hypertrophy, 248; dilatation, 250; failure of compensation, 252; myocarditis, myocardial degeneration, 253; rupture, aneurysm of the heart, 256; new growths and parasites, rheumatic fever, 257; chorea, 264; endocarditis, chronic endocarditis, 266; aortic stenosis, aortic regurgitation, 268; mitral disease, 270; mitral stenosis, 272; right-sided valvular disease, diagnosis, prognosis, and prevention of valvular disease, 273; treatment of chronic cardiac disease, 276; malignant endocarditis, 280;

DISEASES OF THE ORGANS OF CIRCULATION—*continued*

PAGE

effort syndrome, 283 ; congenital malformations, 286 ; pericarditis, 288 ; adherent pericardium, 291 ; chronic constrictive pericarditis, hydropericardium, 292 ; pneumo-hydropericardium, hæmopericardium, angina pectoris, 293 ; **diseases of the blood vessels**, infective arteritis, 297 ; chronic arterial degenerations, 298 ; arterio-sclerosis, 300 ; high arterial pressure, 301 ; intermittent claudication, 304 ; erythromelalgia, 305 ; aneurysm, 306 ; congenital coarctation of the aorta, Raynaud's disease, 310 ; phlebitis, 311 ; thrombosis and embolism, 312 ; angio-neurotic œdema, 316.

DISEASES OF THE ORGANS OF DIGESTION 318—421

Examination of the abdomen, 318 ; the acute abdomen, 320 ; stomatitis, oral sepsis, 321 ; thrush, 323 ; obstruction of the œsophagus, 324 ; achalasia, 325 ; diverticula, 326 ; **diseases of the stomach and duodenum**, examination of the stomach, X-rays, 327 ; test meals, 328 ; dyspepsia, 332 ; aerophagy, 338 ; gastroptosis, 339 ; hysterical vomiting, cyclical vomiting, 341 ; acute dilatation of the stomach and duodenum, gastritis, 342 ; peptic ulcer, 344 ; gastro-jejunal and jejunal ulcers, 350 ; chronic dilatation, 351 ; hour-glass contraction, 352 ; congenital hypertrophic stenosis, carcinoma, 353 ; benign tumours, 356 ; **diseases of the intestine**, constipation, 356 ; alimentary toxæmia, 359 ; diarrhœa, 361 ; hæmorrhage, colic, 362 ; enteritis, 363 ; food-poisoning, cœliac disease, 367 ; phlegmenous enteritis, colitis, 368 ; appendicitis, 371 ; diverticulosis, 374 ; tubercle, new growths, and syphilis, 376 ; intestinal obstruction, 377 ; intussusception, 380 ; Hirschsprung's disease, 382 ; **diseases of the liver**, liver function and functional tests, 383 ; jaundice, 384 ; ascites, 388 ; liver abscess, 390 ; common infective hepatic jaundice, 390 ; acute necrosis of the liver, 391 ; cirrhosis, 393 ; syphilis, and ulcers, 397 ; new growths, 398 ; fatty liver, 398 ; perihepatitis, 401 ; pylephlebitis, 402 ; functional test of the biliary apparatus, 403 ; cholecystitis, 404 ; gall stones, 405 ; suppurative cholangitis, 407 ; functional tests of the pancreas, 408 ; acute pancreatitis, 410 ; chronic pancreatitis, 411 ; calculi, 412 ; neoplasms and cysts, acute peritonitis, 413 ; subphrenic abscess, 416 ; chronic peritonitis, tuberculous peritonitis, 417 ; peritoneal effusions, new growths, 419.

DISEASES OF THE BLOOD, SPLEEN, AND LYMPHATIC SYSTEM 422—458

Examination of the blood, 422 ; an hæmopoietic (deficiency) anæmias, 429 ; chlorosis, 430 ; simple achlorhydric anæmia, 431 ; pernicious anæmia, 432 ; agranulocytosis, 435 ; an hæmopoietic anæmias of childhood, hæmolytic anæmias, acholuric jaundice, 436 ; Lederer's anæmia, splenic anæmia, 437 ; leukæmia, 438 ; chloroma, polycythæmia rubra, erythræmia, 442 ; erythrocytosis, hæmoglobinæmia, 443 ; paroxysmal hæmoglobinuria, 444 ; methæmoglobinæmia and sulphæmoglobinæmia, purpura, 445 ; hæmophilia, 448 ; blood transfusion, 449 ; reaction of the blood and acidosis, 450 ; diseases of the spleen, 453 ; Gaucher's disease, Niemann-Pick's disease, Hand-Christian's disease, diseases of the lymphatic system, 455 ; Hodgkin's disease, 456.

DISEASES OF METABOLISM AND INTERNAL SECRETION 459—504

The basal metabolism, 459 ; diabetes mellitus, 460 ; diet tables, 474 ; hypoglycæmia, 479 ; the thyroid gland, goitre, exophthalmic goitre, 482 ; myxœdema, 485 ; cretinism, 487 ; the parathyroid glands, hyperparathyroidism, 488 ; tetany, 488 ; the thymus gland, 490 ; the suprarenal capsules, 491 ; Addison's disease, 492 ; tumours, 493 ; the pituitary gland, 494 ; acromegaly, 495 ; hypopituitarism, basophil adenoma, 496 ; diabetes insipidus, 497 ; the pineal gland, the gonads, the female organs, 498 ; eunuchism, eunuchoidism, 499 ; hyper- and hypo-genitalism, 500 ; obesity, 500 ; infantilism, 503 ; glycogen disease (in Appendix), 504.

DISEASES OF THE URINARY ORGANS 505—553

Examination of the kidney and bladder, 505; examination of the urine, 506; reaction, 508; albuminuria, 510; hæmaturia, casts, 513; estimation of the renal functions, 515; Bright's disease, 517; acute nephritis, 520; sub-acute glomerulo-tubal nephritis, 525; chronic glomerulo-tubal nephritis, 528; arteriosclerotic kidney, 532; bacteriuria and bacilluria, 534; pyelo-nephritis (pyelitis), 535; metastatic nephritis, perinephritis and perinephric abscess, 538; tuberculosis, 539; hydronephrosis, 541; new growths, 544; cystic disease, 545; movable kidney, 546; calculus, 547; functional albuminuria, 551.

DISEASES INVOLVING BONES, JOINTS AND FASCIÆ 554—568

Infective arthritis, the rheumatic diseases, fibrositis, 554; rheumatoid arthritis and osteo-arthritis, 556; gout, 561; hypertrophic pulmonary osteo-arthropathy, 565; achondroplasia, osteogenesis imperfecta, 566; osteitis deformans, 567.

DISEASES DUE TO CERTAIN DEFICIENCIES IN DIET 569—583

Accessory food factors, 569; beri-beri, 570; epidemic dropsy, 572; pellagra, 573; scurvy, 574; rickets, 577; osteomalacia, 581.

SOME CHRONIC INTOXICATIONS 584—591

Alcoholism, delirium tremens, 584; carbon monoxide poisoning, 586; lead poisoning, 587; mercurial poisoning, 590; arsenical poisoning, 591; manganese poisoning, 591.

DISEASES OF THE NERVOUS AND MUSCULAR SYSTEMS 592—763

Applied anatomy and physiology, 593; blood supply of the central nervous system, 605; cervical sympathetic fibres, cerebro-spinal fluid, 606; lesions of peripheral nerves and nerve roots, lesions of the spinal cord, 607; lesions of the brain, 609; clinical examination of the nervous system, 617; **diseases of the nerves**, 633; olfactory, optic, 634; third, fourth and sixth, 635; fifth, 636; facial, 637; auditory and vestibular, 638; glosso-pharyngeal, vagus, 640; spinal accessory, hypoglossal, 641; upper cervical, 642; phrenic, posterior thoracic, circumflex, 643; musculo-spiral, ulnar, 644; median, brachial plexus, 645; cervical ribs, 647; sciatic, popliteal, 648; sciatica, 649; meralgia paræsthetica, multiple neuritis, 651; localised muscular spasm, hiccup, **diseases of the spinal cord**, 655; compression, 656; tumours, 661; myelitis, 662; hæmorrhage, 666; disseminated sclerosis, 667; syringomyelia, 672; tabes dorsalis, 675; subacute combined degeneration, 681; Friedreich's ataxia, 684; peroneal muscular atrophy, 685; motor neuron disease, 686; Landry's paralysis, 688; senile paraplegia, 689; **meningitis**, suppurative, 690; syphilitic, 692; pachymeningitis interna hæmorrhagica, 693; spinal meningitis, 694; **diseases of the brain**, cerebral hæmorrhage, 695; cerebral embolism and thrombosis, 698; chronic cerebral softening, 701; thrombosis of cerebral sinuses, 702; sub-arachnoid hæmorrhage, 703; encephalitis, 704; encephalitis lethargica, 705; abscess, 711; cerebral contusion, 712; infantile cerebral diplegia, 715; amaurotic family idiocy, 716; cerebro-macular degeneration, Schilder's encephalitis, cerebellar atrophy, 717; hepato-lenticular degeneration, paralysis agitans, 718; tumours, 721; chronic hydrocephalus, 732; general paralysis of the insane, 735; Huntington's chorea, 737; epilepsy, 738; infantile convulsions, 745; migraine, 746; myoclonus, 749; paramyoclonus multiplex, the tics, 750; spasmodic torticollis, 751; writers' cramp and allied neuroses, 752; neuralgia, trigeminal neuralgia, 754; **diseases of the muscles**, muscular atrophy, 755; progressive muscular dystrophy, 756; Thomsen's disease, myotonia atrophica, 759; amyotonia congenita, family periodic paralysis, 760; myasthenia gravis, 761; other disorders of muscle, 762.

MENTAL DISEASES 764—823

Psychological principles, 764; classification, 768; methods of psychiatric examination, 770; the psychoneuroses, anxiety neurosis, 777; hysteria, 785; affective reaction types, the manic-depressive psychoses, 793; involutional melancholia, 797; schizophrenic reaction types (dementia præcox), 799; paranoia, 804; paraphrenia, organic reaction types, 806; infective exhaustive psychoses, 807; presbyophrenia, Alzheimer's disease, 808; psychopathic reaction types, 809; mental deficiency, 810; microcephalic amentia, 812; Mongolian aments, sclerotic amentia, idiots savants, 813; **legal relationships**, lunacy certification, 914; mental deficiency, testamentary capacity, criminal responsibility, 820.

DISEASES OF THE SKIN (DERMATOSES) * 824—983

Primary lesions, 824; **diseases caused by infective organisms—ultra-filterable viruses**, 825; molluscum contagiosum, warts, 826; herpes simplex, 827; herpes zoster, 829; **bacterial diseases**, 832; streptococcal infections, impetigo contagiosa, 833; ecthyma, dermatitis gangrenosa infantum, 836; intertrigo, 837; streptococcal fissure, 838; relapsing streptococcal lymphangitis, eczematoid streptococcal eruption of the scalp, 839; napkin rash, 840; staphylococcal infections, 841; staphylococcal pustule, 842; miliaria rubra, 843; boils, 844; carbuncle, pemphigus neonatorum, 846; multiple abscesses of infants, 847; sycosis coccigenica, 848; sycosis nuchæ, acne necrotica, 850; hidradenitis, 851; granuloma pyogenicum, dermatitis infectiosa eczematoides, 852; acrodermatitis continua, 853; seborrhœic state and associated infections, 854; pityriasis simplex, 859; comedo, acne vulgaris, 860; seborrhœic dermatitis, 862; tuberculosis, lupus vulgaris, 864; lupus verrucosus, 868; the tuberculides, 869; sarcoids, 874; soft sore, 875; rhinoscleroma, 877; **diseases due to fungi**, favus, ringworm, 878; trichophytides, microsporides, epidermophytides, favides, 884; tinea versicolor, 885; erythrasma, leptothrix, 886; oidiomycoses, 887; **spirochætal diseases**, venereal warts, **metazoal diseases**, 888; pediculus capitis, pediculus vestimentorum, 889; pediculus pubis, 890; scabies, 891; **diseases classified according to their morphology**, the erythemas, 893; erythema multiforme, 894; erythema annulare centrifugum, granuloma annulare, 896; erythema nodosum, 897; erythema pernio, 899; erythema ab igne, 900; lupus erythematosus, 901; rosacea, 904; urticaria, 906; urticaria pigmentosa, 910; pruritus, 911; prurigo, 912; prurigo simplex acutus, 916; prurigo of Hebra, 918; prurigo of Besnier, 919; prurigo nodularis, 922; summer prurigo, 923; hydroa vacciniforme, summer prurigo (Hutchinson), 924; light sensitiveness, 925; prurigo hiemalis, dermatitis herpetiformis, 927; dermatitis venenata and toxic eruptions, 929; eruptions caused by drugs ingested, 930; eruptions caused by drugs applied externally, traumatic and solar dermatitis, 931; eczema, 932; erythemato-squamous eruptions, pityriasis rosea, 940; psoriasis, 941; the erythrodermias, 946; pityriasis rubra, premycosic erythrodermia, 947; leukæmic erythrodermia, pityriasis rubra pilaris, 948; papular eruptions, lichen planus, 949; lichen nitidus, 953; parapsoriasis, parakeratosis variegata, 955; vesicular eruptions, cheiropompholyx, 956; bullous eruptions, pemphigus, pemphigus acutus malignus, pemphigus vulgaris, 958; pemphigus foliaceus, pemphigus vegetans, epidermolysis bullosa, 960; hyperkeratoses of the skin, callosites and corns, 961; keratosis, keratosis pilaris, keratosis pilaris atrophicans, keratosis follicularis, 962; cornu cutaneum, ichthyosis, 963; atrophic and dystrophic conditions of the skin, sclerodermia, 964; sclerema neonatorum, atrophodermia neuritica, striæ et maculæ atrophicæ, 965; xerodermia pigmentosa, alterations of pigment, 966; lentigo, chloasma uterinum, 967; ochronosis, albinism, vitiligo, 968; acanthosis nigricans, 969; affections of the sweat glands, anomalies of secretion, 970; miliaria, affections of the sebaceous glands, milium, adenoma sebaceum, sebaceous cysts, 971; affections of the hair and hair follicles, alopecia,

DISEASES OF THE SKIN (DERMATOSES)—*continued*

972; alopecia symptomatica, 973; calvities, 974; alopecia areata, 976; new growths in the skin, fibroma molluscum, Recklinghausen's disease, cheloid, myoma, neuroma, lymphangioma, xanthoma, 981; mycosis fungoides, 982.

DISEASES OF THE TROPICS 985—1114

Introduction, 985; clinical examination, 986; special therapy, 987; heat stroke and other maladies, 988; food poisoning, and diet deficiencies, 990; tropical macrocytic anæmia, 991; tropical dysfunction of the gastro-intestinal tract, tropical sprue, 992; **infectious diseases of the tropics—filterable viruses**, 995; hydrophobia, 996; yellow fever, 998; dengue, 1001; sandfly fever, 1002; climatic bubo, 1003; **rickettsial diseases**, 1004; louse typhus, 1005; Rocky Mountain fever, 1007; tick typhus, 1008; Japanese river fever, **bacterial diseases**, bacillary dysentery, 1009; cholera, 1013; leprosy, 1016; undulant fever, 1022; tularæmia, 1025; oroya fever, 1026; tropical myositis, 1027; **mycoses**, 1028; moniliasis, rhinosporidiosis, maduramycosis, 1028; coccidioides, 1029; **spirochaetal diseases**, yaws, 1030; goundou, gangosa, 1031; juxta-articular nodes, 1032; louse relapsing fever, 1033; tick relapsing fever, 1034; Weil's disease, 1035; Japanese, seven-day fever, rat-bite fever, 1038; **protozoal diseases**, malaria, 1039; blackwater fever, 1046; kala-azar, 1049; oriental sore, American dermal leishmaniasis, 1052; African trypanosomiasis, 1053; South American trypanosomiasis, amœbic dysentery, 1056; amœbic hepatitis, 1059; ciliate dysentery, flagellate diarrhœa, giardiasis, 1063; **helminthic diseases**, trematodes, fascioliasis, 1064; paramphistomiasis, 1065; clonorchiasis, paragonimiasis, 1066; vesical schistosomiasis, 1067; intestinal, 1070; Asiatic, 1071; heterophyidiasis, cestodes, *Tænia solium*, 1072; *Tænia saginata*, *Dipylidium caninum*, *Diphyllbothrium latum*, 1073; *Sparganum mansoni*, *S. proliferum*, cysticercosis, 1074; echinococcosis, 1076; hydatid of the liver, 1078; of lung, 1080; of brain, renal, *Hymenolepis nana*, 1081; nematodes, strongyloidiasis, 1082; *filaria bancrofti*, 1083; *F. perstans*, 1084; *F. ozzardi*, *Loa loa*, 1085; onchocerciasis, 1086; dracontiasis, 1088; trichiniasis, 1089; œsophagostomiasis, 1090; ancylostomiasis, 1091; ascariasis, 1093; trichuriasis, oxyuriasis, 1094; **diseases due to larvæ**, myiasis, 1095; tongue-worms, **bites and stings**, 1097; mites, 1098; ticks, spiders, 1099; scorpions, centipedes, biting leeches, 1100; snake bite, 1101; poisonous fishes, 1104; **tropical skin diseases**, chigger disease, craw-craw, 1105; veldt sore, tropical ulcer, 1106; pemphigus contagiosus, tinea, 1107; **tropical diseases of unknown origin**, ainum, big heel, onyalai, 1109; chiufa, chappa, mossy foot, 1110; ulcerating granuloma, 1111.

THE PRACTICE OF MEDICINE

INTRODUCTION

A THOROUGH knowledge of every disease requires an acquaintance with several separate branches of study, which are as follows :—

Ætiology, the study of its causes in general. *Pathology*, the study of its causes within the body, and the processes resulting therefrom. *Morbid Anatomy*, the alterations in the structures caused by it. *Symptoms*, the indications—subjective on the part of the patient, and objective to the physician (usually called *physical signs*)—by which we arrive at a knowledge of what is wrong. *Diagnosis*, the method of distinguishing from one another the diseases that may have symptoms more or less nearly alike. *Prognosis*, the art of foretelling the course, duration, and termination of any given case. Finally, the *Prevention* of disease (prophylaxis), and the *Treatment* of disease when it occurs, both of which are the chief aims of the study of the science and art of medicine.

Ætiology. The causes of disease are commonly divided into *predisposing* and *exciting*, but no broad line can be drawn between them. A predisposing cause may be in operation for a great length of time without the disease being produced, whereas the exciting cause is usually only of short duration; but conditions which act as predisposing causes at one time may act as exciting causes at another. *Ætiology* strictly covers the whole of the causation of disease, but it is perhaps more often applied to the remoter causes and to those conditions which are constantly associated with a disease, although we are unable to say how they influence its occurrence. The relations to disease of age, sex, climate, hygienic surroundings, food, and preceding illnesses are commonly considered under this heading. On the other hand, changes taking place in the body, immediately preceding or causing the disease, are considered rather as pathological processes than ætiological factors.

Pathology is sometimes used to signify the study of diseased structures, but it is better limited to the study of diseased processes—that is, practically, the influence which the causes of disease have upon the function and structures of the body; while **morbid anatomy** or **pathological anatomy** describes in detail the diseased structures themselves.

Symptomatology is the study of the symptoms of any disease, and associated with this and with its morbid anatomy we have to consider what have been called **complications** and **sequelæ**. Emphasis has with perfect right been recently laid on the study of the early symptoms of disease, so that treatment may be carried out in the earliest stage.

Complications are certain lesions or symptoms which are the result of the original disease, but only occur from time to time, and are not regarded as a necessary part of the disease; thus abscesses are a complication of enteric fever, hæmoptysis a common complication of pulmonary tuberculosis, parotitis a very rare complication of pneumonia. But the term is applied somewhat arbitrarily; for instance, in enteric fever rose spots and diarrhoea are not universally present, and yet they are regarded as part of the disease, and never as complications. We must regard in a different light the case where one disease occurs at the same time as another, but, as far as our own knowledge goes, is quite independent of it; the complication may seem to be purely accidental, yet the

primary disease may have disposed the individual, in some way not hitherto ascertained, towards the acquirement of the second. Two common cases are (1) the complication of any slight or severe local disorder by an infectious disease, such as scarlet fever, caught by contact; (2) the termination of some chronic nervous disease, like hemiplegia or locomotor ataxy, by pneumonia or bronchitis.

A sequela is a symptom or lesion appearing or persisting after the original disease has subsided.

Diagnosis is the recognition of diseases by certain symptoms, physical signs or facts in the history of the cases which, taken together, indicate that the patient is suffering from a particular ailment. By *differential diagnosis* is meant a knowledge, in any given disease, of all the other diseases which most clearly resemble it and the points of difference upon which reliance may be placed to distinguish it.

If two complaints are likely to be confounded together, and one is much more serious than the other, a wrong decision that the less serious is present is dangerous for the patient, since his undiagnosed complaint may progress to a fatal point without proper treatment. On the other hand, a wrong decision that the more serious is present may cause the physician to alarm the patient unnecessarily and ultimately bring discredit upon himself. Especially is it desirable in the case of the commoner, temporary, and more curable complaints to bear in mind the possibility of their being simulated by rarer and more dangerous diseases. The confusion of angina pectoris with various forms of chronic indigestion and of appendicitis with acute indigestion are instances which too often occur. Probability is an important element in diagnosis. In exceptional instances a disease may present a physical sign, symptom, or indication which is not caused by any other known condition. Such a sign or symptom is said to be *pathognomonic* of the disease in question. As a matter of fact, there are very few *pathognomonic symptoms*.

It will have been gathered from the remarks on diseases that by diagnosis we shall always aim at finding out the *primary* lesion; thus we must not be content with calling any pain rheumatism or neuralgia, but we must try to find out whether such pain is caused by pressure on a nerve, by inflammation of a nerve, or by degeneration of nerve tracts. But in many cases the patient suffers from numerous symptoms: pain, cough, sickness, dropsy, albuminuria, and others. As a rule, we should try to see how far all these conditions may be due to one single primary lesion, such as valvular disease of the heart or granular disease of the kidney; but we must not forget that frequently two or more independent lesions co-exist, and produce a complex arrangement of symptoms.

Prognosis. Successful prognosis requires a thorough acquaintance with the natural history of every disease, with the extent to which the disease is influenced by age, sex, and other ætiological factors, and a careful judgment on the variations of the patient from day to day.

The questions that arise in prognosis are such as these: Will the patient recover? Will he recover completely or be left with any organ damaged? Will he ever have the disease again? If it is a fatal disease, how long will he live?

In the early days of a disease the question of recovery can only be answered by a consideration of the percentage mortality as shown by statistics. As the case proceeds the rapidity or severity of the symptoms, the conditions of the circulation, the ability to take food, and the integrity of the nervous system are the points which have most bearing on one's opinion. In practice, prognosis is often of the greatest importance for the physician's credit, and a hasty conclusion which turns out wrong is often remembered against him more than any want of success in treatment.

When in this volume it is stated that the prognosis of any disease is favourable,

this means, not that it is never fatal, but that *most* cases recover ; if any particular symptom or complication renders the prognosis *less* favourable, this means that the percentage mortality of cases with such complication is greater than it was before or without the complication.

Prevention. The *prevention* or *prophylaxis* of disease may be looked at from two points of view : (1) that of the community, and in this connection it is known as the study of *hygiene* or *public health*, and involves all measures by which the community endeavours to ward off all external influences adverse to health ; (2) that of the individual, by which the body itself may be prepared against the operation of the causes of disease, partly by judgment in matters of diet, exercise, clothing, etc., and partly by such special treatment in relation to particular diseases as is effected by the injection of typhoid and plague vaccines in the bacterial infections, and vaccination against small-pox and antirabic inoculations in the filterable virus diseases. For efficient prevention in this sense it is essential to recognise the very beginnings of disease, so that remedies may be applied before the disease becomes established and irremediable structural alterations in organs have taken place. For this purpose the early symptoms exhibited by patients require special study. Prevention of this kind is of growing importance in medicine, and it will be considered in detail in the appropriate places.

Treatment. In this we should aim first at the removal of the cause where this is possible ; if not, we may succeed in neutralising its influence. One or other of these methods may suffice to cure all the symptoms and troubles of the patients ; but though the numbers of specific remedies are steadily increasing with the progress of research we are still in most cases called upon to deal directly with the symptoms, using remedies that have no influence upon the underlying disease. We must, when doing this, never forget that such symptoms hold a position secondary in importance to that of the disease which causes them. Lastly, we must in all cases counteract the tendency to death, which may, indeed, be the natural course of the disease, or may arise rather as an accident from some infrequent complication. As an example we may take phthisis, which is due primarily to the invasion of the lung by the tubercle bacillus. The removal of this, when once it has obtained a footing, cannot be directly effected. Its influence can be neutralised by the best hygienic surroundings, by fresh, bracing air, and by special climates which enable the body to resist the action of the bacillus. In the meanwhile there are numerous symptoms—cough, expectoration, pain, sweating, diarrhœa—which will diminish as the condition of the lung improves, and which can be also controlled by suitable medicines. In addition serious complications may arise, especially hæmoptysis, or spitting of blood, by which life is directly threatened, and such a death may be averted by proper therapeutic means. A short account of the various methods of treatment may be given here.

Rest. In many diseases, *e.g.*, acute infections, rest is the most valuable method of general treatment we possess. The presence of pain is one of its most important indications, as was pointed out by Hilton in his book “ Rest and Pain.” The subject of rest will be constantly referred to throughout this book.

Diet. Food consists of proteins, fats and carbohydrates, and the proportions of these substances may have to be altered in certain cases. The proportion of carbohydrate to fat is important in diabetes. Again, flesh foods contain purin substances which may be harmful in gout, and strict moderation must be exercised, whereas in sprue, coeliac disease and idiopathic steatorrhœa high protein, low fat, and low carbohydrate diets are indicated. Patients confined to bed require less food than persons taking active exercise ; in febrile states more food will be needed than when the temperature is normal, because the energy output is greater ; at the same time, it must be taken in an easily digestible form, and the latter applies to various gastro-intestinal diseases. The diet must

be arranged so that it contains sufficient of the various *accessory food substances*, or *vitamins*, the presence of which are essential to life.

Artificial Feeding in Infancy. It is not possible to deal with this subject adequately in a general text-book, and the following should be regarded only as a summary.

The food requirements of a normal infant depend on age, weight and individual idiosyncrasies. It is usually best to consider the age and weight first, and later to modify the feeds according to the individual needs, which vary greatly in different infants, according to vigour, temperament and power of digestion of various constituents. The nervous, restless, wakeful child requires more food to support its increased metabolism in order to leave a sufficient margin for proper growth. Frequency of feeding varies with the capacity of the stomach and the rate at which it empties: as far as possible it should be assured that the stomach is empty before the next feed is given: it is impossible to fix an arbitrary rule. Increase in weight must be carefully watched. Usually three-hourly feeding is satisfactory up to the age of three months, after which the interval may be increased to four hours. Many infants thrive on four-hourly feeding in the early months, in which case the longer interval is desirable as being more likely to ensure emptying of the stomach.

From the point of view of growth, protein is the most important constituent of the food, but fat is important, partly on account of the fat-soluble vitamins. Sugar is a valuable means of meeting calorie requirements, but tolerance to both sugar and fat varies greatly in different infants.

In working out a first *trial* feed, it is usually best to consider what the weight of the child should be for its age, taking account of the birth-weight, rather than basing calculations on the actual weight. If the child's weight is very much less than the "forecast" weight, there would be a great risk of intolerance to a sudden increase in food, and it is better to start at a lower level, increasing the intake every few days till a satisfactory rate of growth is obtained, and decreasing if there are any signs of intolerance. Using the "forecast weight" as a basis, the average requirements for the twenty-four hours may be taken as:

$$\begin{aligned}\text{Total fluid, in ounces} &= \text{weight in pounds} \times 3 \text{ (in early months).} \\ &\quad \times 2 \text{ (in later months).} \\ \text{Milk, in ounces} &= \text{weight in pounds} \times 1.75. \\ \text{Total calories required} &= \text{weight in pounds} \times 45.\end{aligned}$$

Whole cow's milk provides approximately 21 calories per ounce. The remainder of the calorie requirement is furnished by sugar. A level teaspoonful of cane sugar supplies about 15 calories; of lactose or dextrimaltose, about 10 calories. It should be noted that rather more than half the calorie value of the milk is provided by the fat, and that if for any reason the fat content is reduced by skimming it will be necessary to increase the amount of other constituents in the feeds, usually by increasing the proportion of milk to water: it is dangerous to use an excess of carbohydrate. If the capacity of the infant's stomach is small it may be necessary to increase the proportion of milk to water: in this case the milk may be rendered more digestible by adding two minims of lactic acid to each ounce of milk: in adding this, the milk must be kept constantly stirred to secure an even emulsion.

It is often possible, on a first examination, to recognise the type of infant who will require considerable modification of the above formula.

When an infant has been seriously underfed, increases must be slow, but sufficiently rapid to allow for the increased demands of growth and to stimulate the powers of digestion.

It is often convenient to use one of the forms of dried milk. In evaporation, approximately $\frac{2}{3}$ of the weight of the milk is lost.

In all cases of artificial feeding it is desirable to give additional quantities of

vitamin C. At the age of three months, a daily allowance of one tablespoonful of orange juice, diluted with an equal quantity of water, may be given between feeds, and the amount gradually increased up to 2 oz. If this is not tolerated, tomato juice forms a good substitute. If the percentage of fat has been decreased, vitamins A and D should be given in concentrated form.

Climate is generally described as "tonic" or "bracing," and on the other hand as "relaxing" or, if this word has unpleasant associations, as "sedative." From the point of view of clear thinking the use of these words might well be discontinued. A "bracing" climate means a climate of marked cooling power. Leonard Hill's observations with his kata-thermometer show that cooling power depends on three factors: temperature, humidity, and the movement of air. Hence a bracing climate must mean one possessing a cool, dry, breezy atmosphere, while a relaxing atmosphere will be hot, moist, and still. British spas, with the possible exception of Bath, belong to the former category, and this is an advantage, because at the end of the cure, which usually lasts three months, the patient can go straight back to his ordinary occupation. British seaside resorts have a wonderful variety of climate. In the South-West they approximate to the French and Italian Riviera, but as there are usually more clouds in the sky the fall in temperature at night is less marked; the days are not so hot and the nights are not so cold. The resorts in the East and North-West are cool, while those in the South-East may be regarded as intermediate.

England possesses no mountain climate, and if such is required patients must go to Switzerland, or farther afield to the High Tatra in the Carpathians. The action of such a climate is due to the reduced pressure of oxygen, which appears to stimulate the production of adrenaline, causing a rise of blood sugar, an increase in the formed elements of the blood which are at first pressed out of the spleen; there is an increase of glutathione, the ferment first prepared *in vitro* by Sir Gowland Hopkins; and certain substances appear in the serum, known as hæmopoietins, which have the property of hastening the regeneration of blood after hæmorrhage. A point of some interest is the rise of serum calcium, which means that the sympathetic becomes less excitable and the thyroid less active. This fact was discovered empirically a number of years ago when an exophthalmic goitre patient, sent from Vienna to the High Tatra, did remarkably well; the mountain climate is now recognized to be of value in this disease, and insured patients are sent to the Tatra. No patient with cardiac insufficiency should be sent to the mountains; but it has long been known that patients with phthisis and surgical tuberculosis do well there. The deficiency of oxygen must clearly be a responsible factor, since among other things this stimulates the production of red cells and counteracts the anæmia.

What is meant by "fresh air" in the treatment of phthisis in this country? "Fresh air" does not mean air with an unusually large amount of oxygen in it, because the percentage of oxygen is much the same in the country as in the town. "Fresh air" treatment of phthisis in this country must mean treatment by cold, since this has been found to increase the metabolism of the resting subject, and patients who live out of doors all the time have better appetites and eat more food to provide fuel for their increased metabolism. The three general factors in treatment that can be supplied by the tuberculosis sanatoria of this country are fresh air with its increased cooling power, rest, and good food. A fourth factor—diminished oxygen supply—is only present in the mountains. *Sunlight*, an antiseptic agent and elaborator of vitamin D in the skin, is a fifth factor suitable for surgical tuberculosis and septic states, but this is not given in phthisis, since it causes hæmoptysis from congestion of the lungs—at least, that is the Swiss experience.

Drugs. No specific drugs are available for the bacterial and filterable virus infections, but a large number are known which cure protozoal and helminthic diseases. Quinine, atebrian and plasmoquine in malaria, emetine in amœbic

dysentery and abscess of the liver, salvarsan in the spirochætal diseases like syphilis, yaws, relapsing fever and rat-bite fever, Bayer 205 and tryparsamide in sleeping sickness, and pentavalent antimony compounds, like neostibosan in kala-azar, may be cited as a few examples. Many of the intestinal helminths can be cured by specific remedies, and trivalent antimony preparations, like tartar emetic and foudadin, are effective in eradicating bilharzia parasites from the portal system of man. The British Pharmacopœia gives the official list of drugs which are required in treatment, but fresh drugs are constantly being introduced, and older drugs not now in the Pharmacopœia may still be of service. Besides the older methods of administration by the mouth and rectum, and through the skin by means of ointments and by medicated baths, drugs are now introduced by hypodermic, intramuscular, intravenous, and intraspinal injection, and also by *ionisation* or *cataphoresis*. In this method ionisable salts, of which one or both of the component elements are efficient drugs, are applied to the skin; and, by means of a galvanic current, one or other of the ions is driven into the tissues, and exerts the desired effect.

Dosage. Full details of adult dosage are given in the Pharmacopœia; but the problem arises as to the correct proportions to be given to children or undersized adults. Again, in carrying out the "sugar tolerance test" or "urea output test," what dose of sugar or urea should be given to a child? Unless there is any idiosyncrasy in the case of children it is best to calculate dosage as proportional to $\frac{2}{3}$ power of the body weight. If a man of 10 stone (140 lb.) requires the full dose, then the following proportional doses have been calculated according to this rule:—

Weight (lb.)	180	160	140	120	100	80	60	55	50	45	40	35
Dose ...	1.18	1.1	1.0	0.9	0.8	0.69	0.57	0.53	0.5	0.47	0.43	0.4

Organo-therapy or Opothrapy. As special forms of drugs, which can be given internally or *per rectum*, or by subcutaneous injection, must be mentioned the extracts of various organs of animals (thyroid, suprarenal gland, pituitary body, insulin) which may be made to supply defects in the corresponding organs in the human subject.

Antitoxic and Antibacterial Sera. These are of great value in some infectious bacterial diseases—for instance, in diphtheria. They consist of the serum of an animal which has been rendered immune to the particular disease; and the serum contains anti-bodies which will neutralise the disease in the human patient (*see p. 14*). They are standardised by careful experiments upon animals. They may be injected subcutaneously, or into the muscles, or into the veins, or within the theca of the spinal column.

Bacterial Vaccines. A vaccine is a solution containing up to several million dead bacteria of the same species as those of the disease requiring treatment, and preferably cultivated from material obtained from the patient to be treated. The injection of these bacteria in gradually increasing amounts increases the anti-bodies in the patient's serum, raising the immunity.

Heat. Besides the local application of warmth for purposes of stimulation or counter-irritation, and of heat for its destructive effects (cautery), *radiant heat*, by means of incandescent electric lights or *infra-red* radiation is employed for the local treatment of rheumatic joints and allied conditions.

Diathermy is a more recent method of applying heat locally. The heat is produced by continuously maintained high frequency currents, and in this form it penetrates more deeply into the part, *e.g.* a joint, than any heat, that can be borne, supplied by sources external to the limb.

Finsen Light. This light treatment of lupus and rodent ulcers consists in directing an intense light upon the diseased part for specific periods of time. The light consists of violet and ultra-violet rays, and is produced by an arc-light from which the heat rays are cut off.

Röntgen Rays or X-rays. The powerful effects of these rays are well known, both for good and evil. Constantly playing upon the unprotected skin, as in the case of X-ray operators, they have caused intense and incurable dermatitis, leading on to carcinoma. Death has also been caused by their destructive action on the blood-forming organs, producing *aplastic anæmia*. Used with proper precautions for limited periods, they modify the growth of cells in the body, and have been of value in the treatment of rodent ulcer, carcinoma, Hodgkin's disease, leukæmia, syringomyelia, ringworm, and other affections. In deep X-ray therapy the less penetrating rays are filtered off and the more penetrating rays alone used. Structures lying deep inside the body, *e.g.* the uterus, affected with carcinoma, can be reached by the rays and, by varying the direction from which the rays come, in other words the portal of entry, the skin is saved.

Radium. The rays emanating from this substance have powerful effects on all living tissues and especially on cancer cells.

Electricity. The chief uses of this force have been in the treatment of paralysis and other nervous diseases. Muscles which cannot be stimulated by the will can be made to contract by electric stimulation, so long as their nutrition is normal and they are not the subject of atrophy. This contraction, effected at stated intervals, maintains the circulation of blood and lymph in the muscles, and facilitates the return to health. Such contractions can be effected by the faradic or by interruption of the continuous current. Many painful neuralgic affections are benefited by a continuous current of electricity. Another application of electricity now often used is that of high-frequency currents. These are currents of high potential, perhaps 10,000 volts, alternately positive and negative, and changing their sign about every millionth part of a second. They are consequently too rapid to stimulate sensory nerves or motor nerves or muscles, which can only respond to stimuli of about $\frac{1}{1000000}$ second duration; nevertheless they have certain effects upon the tissues, which are claimed to be increased cellular activity, changes in the vascular system, and inhibition, *i.e.* diminished susceptibility of the neuromuscular system to ordinary stimuli.

Massage. By massage is meant the manipulation of the soft tissues of the body and limbs by an operator, aiming at assisting the circulation of the blood and lymph to the part, thus stimulating metabolism which is normally produced in the healthy person by active exercise. By its use adhesions round stiff joints are loosened and relaxation more easily obtained. It is valuable as an introduction to normal activity applied to muscles which, owing to injury or prolonged illness, are weak and wasted. In severe nervous strain and in some nervous disorders it is a means of obtaining relaxation of the whole body, and in others it tends to prevent excessive wasting. It will materially lessen the feeling of fatigue in the convalescent period and enable progressive muscular work to be introduced more quickly. To obtain the quickest result the limbs about to be manipulated should be thoroughly warm and relaxed.

In *effleurage* the surface is stroked in an upward or centripetal direction. The hand of the operator should be relaxed and kept in close contact with the skin of the patient; the movement is performed rhythmically by alternate hands, slowly if lymphatic drainage is required and more or less quickly for the venous return. *Petrissage* includes all forms of muscle manipulation. The hands of the operator are placed firmly in contact with the part under manipulation and the muscles are alternately squeezed and relaxed, care being taken to prevent any slipping of the hand on the skin. *Friction* consists of a small circular movement performed by the thumb or finger on areas, for dispersing local tenderness and adhesion. *Vibrations* are fine intermittent movements performed by the fingers or hand, used chiefly over nerves and in cases of persistent flatulence. *Tapotement* includes various forms of *tapping*, *hacking* and *pounding*, a percussion movement

performed with the ulnar surface of the fingers and hand, the closed hand or the heel of the hand, producing local hyperæmia.

Massage movements are mainly centripetal : the hands of the operator should be soft, dry and relaxed. Oil, ointment or liniments should not be used unless specially ordered by the physician.

Passive Movements. This form of treatment is applied to the joints. They may be classified under two headings : *Manipulation*, in which the joint is passively moved in its full range in every direction by an operator, relaxation of the patient being first obtained with or without an anæsthetic, and *continuous traction*, which is obtained by manually drawing the surfaces of the joints apart for a prolonged period, or by some form of weight extension.

The duration of massage is determined by the area of the body to be treated. A limb in which there is acute traumatic swelling or in which there is a diminished blood supply requires five to fifteen minutes, three times a day. The whole body cannot be properly manipulated under forty-five minutes. Massage should only be ordered in those cases in which active work cannot be introduced, and if ordered should only be continued for the period that activity is not possible.

Swedish remedial exercises, Nauheim treatment, Frankel's precision movements and others are various systems of graduated active movements in which the muscles of the body are forced to work, under the direction of the physician or medical gymnast, with the object of providing a daily amount of exercise either locally or generally. Their value is to work up gradually through controlled muscular contraction the joints, the heart, the muscles, the organs of digestion and excretion ; or, as in the case of precision movements, re-establish the function of co-ordination through the nervous system.

This system of work is the only method of restoring the normal function of the muscular system, and massage should only be employed as an introduction to active work. The amount of active work at each treatment should be regulated by the pulse rate charted on a morning and evening chart. In severe debility the pulse may be raised six to 10 beats after each treatment, provided it returns to normal after two minutes' rest ; and in more chronic cases may be raised twenty to thirty beats after exercise, returning to normal after three minutes' rest. A gradually rising pulse may result if the active movements are too rapidly progressed.

As an adjunct to massage and active muscle work, in some conditions various forms of baths have their value in that they increase the action of the skin, and thoroughly warm the part under treatment. For a local part, whirlpool baths or paraffin wax baths will be found the most useful. For the whole body, foam baths are most effective, and can be used in the patient's own home.

Natural Waters. The drinking or application, by baths or douches, of natural waters is one of the very earliest treatments in medicine. To avail themselves of this treatment patients must visit the *Spa*, because waters after coming up from the earth often rapidly age, losing their physical and biophysical properties. Mineral springs come either from relatively superficial geological strata, when they are known as *vadose*, or from deep down in the earth through faults in the strata, when they are warm or hot. When the temperature is 93° F. the body neither gains nor loses heat when immersed ; this is the point of thermal indifference. Such waters are called *thermal*, or if the temperature is much higher *hyperthermal*. In subthermal or cold baths the temperature is much lower, *e.g.* 68° F., when the loss of heat from the body is increased five-fold by immersion.

Classified according to their mineral content, waters in the first place may be hyper- or hypo-tonic according to the concentration ; in the second place, according to their nature, they may be *alkaline*, when they contain metals, such as sodium, potassium, magnesium, calcium or carbonates, borates or silicates ; *saline* containing sulphates, chlorides, nitrates or phosphates ; *acid* containing hydrochloric or sulphuric acid—these are usually volcanic ; *ferruginous* or *chalybeate*, containing

iron; *sulphur* or *sulphuretted* containing sulphides. Then there are qualifying substances present in small amounts in various waters, such as arsenic, carbon dioxide, nitrogen, iodides, bromides and radioactive substances. The treatment by waters, whether mineral or ordinary tap water, is *hydrotherapy* and this science is called *medical hydrology*. Finally, mention must be made of the *peloids*, or muds, which are used for external application; these may be alluvial or volcanic, or consist of peat.

Baths and Douches. By these means heat and cold and mechanical effects may be produced, and so the vasomotor system and the circulation may be affected both locally and generally. Immersion baths, like the ordinary household bath, may be combined with under-current douching with water at a different temperature directed to a special part. In "Massage sous l'eau" streams of water are directed on the patient while massage is applied. Alternate hot and cold douches, the hot air bath, vapour or steam bath, foam bath, whirlpool bath, paraffin wax bath, are different methods used at any institution for physical medicine. The mineral waters at the Spa are also commonly employed for baths; special mention may be made of carbon dioxide baths for circulatory disorders, with waters containing the gas coming out of solution; these may be made artificially. Hot baths are valuable for promoting diaphoresis or sweating.

INFECTIOUS DISEASES

NATURE OF INFECTION

Action of Virus in the Recipient. The virus, or causal agent of the disease, enters the system by the respiratory tract (scarlet fever, small-pox), the throat (diphtheria), the alimentary canal (enteric fever, cholera), the genital mucous membranes (gonorrhœa, syphilis), by the bites of insects (malaria, yellow fever, sleeping sickness), or by coarser lesions of the skin (syphilis, hydrophobia).

If the organism is virulent and the individual susceptible, the entry of the virus is followed by a period of *incubation*, during which no changes are manifest, and which varies generally from two or three to twenty-five days, being constant within limits for each particular disease. During the period of incubation the organisms are developing and multiplying, and elaborating the poisonous products to which for the most part the different symptoms and effects of an infectious disease are due. The micro-organisms are sometimes confined to the seat of inoculation or invasion, while their poisons or toxins alone are diffused through the system (*toxæmia*). Another rather old-fashioned term for this condition is *sapremia*, which however implies that there is a rather extensive area of necrosing tissue, *e.g.* in the uterus, from which toxins are absorbed. Again, the micro-organisms may gain an entrance from some primary focus into the blood stream, remaining there alive, so that living bacteriological cultures may be obtained from samples of blood. Such a condition is called a *septicæmia*. In the last stages of the disease these organisms may be actively multiplying in the blood stream; but ordinarily there is a balance between the rate at which the organisms enter the circulation and the ability of the blood to deal with them by means of its various immunity reactions. In fact, there may be so few organisms present that the bacteriological examination is negative; consequently a negative result does not necessarily exclude a septicæmia.

When a septicæmia is present the micro-organisms may become impacted in different parts of the circulatory system, and thus form fresh foci of disease in the form of metastatic abscesses in different parts of the body. This condition is called *pyæmia*. But metastatic abscesses or pyæmia may arise independently of a septicæmia by minute fragments of clot, *etc.*, containing micro-organisms becoming detached from the primary focus, being washed into the blood stream, and being disseminated throughout the body. The position of the primary infective focus determines to some extent in what organs the abscesses will be situated, owing to the direction of the blood stream, as follows: (1) Where the lesion is situated in the peripheral systemic circulation, *e.g.* in acute osteomyelitis, abscesses or septic infarcts occur primarily in the lung. However, certain minute emboli will succeed in traversing the pulmonary circulation, so that further abscesses may be found in the heart muscle and in other organs. (2) Where the primary focus is in the lung, *e.g.* in chronic bronchiectasis, or in the heart, *e.g.* in infective endocarditis, abscesses or infarcts will occur primarily in the brain and other organs of the systemic circulation. (3) In *portal pyæmia* the primary lesion is some form of ulceration of the parts which drain their blood into the portal vein, *e.g.* an appendix abscess; and secondary abscesses form in the liver, with or without a suppurative pylephlebitis (*see Pylephlebitis*).

Transmission of Infectious Diseases. This is really a branch of Public Health, but a brief notice of it cannot be excluded from a work like this. The infectious diseases having been defined as those in which a virus, or micro-organism, is introduced into the body, it must be here stated that the virus is derived, first, from other human beings ill of the disease directly or indirectly, as in scarlatina, measles, and many others; or, secondly, from animals, as in rabies, anthrax, foot-and-mouth disease; or, thirdly, from the soil or other source independent, as far as is known, of the previous participation of other men or animals in the process, as in tetanus. In many cases, as in scarlet fever and diphtheria, the secretion from the respiratory mucous membrane, in the form of droplets of sputum, is the means by which the poison is conveyed; in others, as in cholera or enteric fever, the faecal discharges; and in others, as in syphilis and glanders, the pus from sores. Increasing importance attaches to the fact that the organisms may persist in the individual for months or years after convalescence is complete, and thus may be the cause of infection in others. This happens in typhoid fever, diphtheria, cholera, cerebro-spinal fever and poliomyelitis, and the persons conveying the infection are called *carriers*.

In an increasing number of diseases it is becoming evident that the virus or micro-organism is conveyed from the sick to the healthy by means of biting or sucking insects, which either take up the infecting agent in blood from the patient's skin and discharge the virus by puncture into the skin of a new host, or discharge on to the healthy skin faeces which subsequently get rubbed into punctures, or otherwise infect it. Thus malaria, yellow fever, and filariasis are conveyed by mosquitoes; sleeping sickness by tsetse flies; typhus by lice; relapsing fever by lice and a similar disease in Africa by ticks; plague by fleas; while the common house fly may possibly have a share in the transmission of cholera, typhoid, infantile diarrhoea, ophthalmia, and some other diseases. In some cases the virus, or micro-organism, undergoes development in the body of the insect.

Mixed Infections. Some of the more familiar instances of mixed infections are the co-existence in the same person of scarlatina with diphtheria, of scarlet fever with whooping-cough, of scarlet fever with chicken-pox, of diphtheria with measles, of whooping-cough with broncho-pneumonia, of tubercle with lobar pneumonia; but the most important and frequent, perhaps, is the secondary invasion of the body in a great number of infectious diseases by the pus-forming organisms, *Staphylococcus pyogenes aureus* and *Streptococcus pyogenes*, leading to suppurative lesions, septicæmia, and pyæmia as complications or sequels of the original disease.

Prevention of Infection. There are three ways by which the transmission of infectious diseases from one person to another, or others, may be prevented. One is by separating the sick from the healthy (*isolation*). Another is by destroying the virus in the sick person, or in whatever clothes, books, room or furniture he may contaminate, or in whatever excreta may pass from him (*disinfection*). If insects are a factor in the contagion, they should be exterminated if possible or, at least, prevented from contact with the sick. The third method is by so modifying the condition of the possible recipient that he becomes insusceptible to the influence of the virus, even if brought into contact with it (*production of immunity; immunisation*).

Isolation. The patient should be placed in a separate room, if possible on a separate floor of the house, which may be screened off by a sheet wetted with a solution of carbolic acid (1 in 40). Thorough ventilation must be as far as possible maintained, as the dilution of the poison by a constant influx of fresh air is a most important part of the process. All unnecessary furniture, curtains and carpets, clothes, etc., to which contagion may adhere, should be removed from the room. The attendants should be, as far as possible, those who are protected by a previous illness; and it should be remembered that their clothes

may convey the disease as they pass from the sick-room to other parts of the house, unless such over-clothing is changed before coming into contact with others. Only such books, papers, or toys should be allowed in the sick-room as may be afterwards burned. Food utensils should be disinfected by being heated in water to the boil.

Quarantine. The quarantine period for persons who have been in contact with patients suffering from an infectious disease is regarded as two days longer than the maximum incubation period which is stated in the description of each disease ; but in the case of diphtheria all exposed persons are in quarantine until shown by bacteriological examinations not to be carriers.

In the case of the infected person himself isolation from susceptible or unprotected persons should be maintained as long as the patient is believed to be infectious. Every case must be taken on its merits ; thus in mild uncomplicated scarlet fever four weeks will suffice, or if anti-scarlet fever serum has been used as little as three weeks may suffice. The Medical Officers of Schools Association has adopted the following as the shortest times which should elapse between the appearance of the rash or other commencement and the return of the patient to his home or school : In rubella, seven days, provided there is no persistence of nasal or other symptoms ; in measles, not less than ten days from the appearance of the rash, convalescence being satisfactorily established ; in mumps, two weeks, including one clear week from the subsidence of all swelling ; in diphtheria, four weeks, providing all discharges have ceased and no specific bacilli can be found in the nasal or pharyngeal mucus ; in pertussis, two weeks free from onset of spasmodic cough or whoop, or in case of persistent whooping four weeks from this date ; in scarlatina, four weeks, provided convalescence is completed and there is no sore throat, discharge from ear or nose, suppurating gland, or eczematous patch, but there should be two weeks' extra convalescence before return to school. In small-pox and varicella, all scabs should have fallen off, and all sores should be healed, particular attention being paid to the scalp.

Disinfection. *Disinfection of the Excreta.* Fæces or urine, *e.g.* in enteric fever, should be covered with lysol (1 in 50), and allowed to stand for at least one hour before being emptied down a W.C. Sputum should be treated similarly, or it may be burnt or boiled.

Disinfection of the Clothing. Linen may be disinfected by soaking in 1 in 50 solution of lysol for one hour ; it may then be wrung out and sent to the laundry. If stained with albuminous matter it should be soaked in water before being put into lysol. Many local authorities remove clothing and bedding, etc., and return it after disinfection by steam ; this is the only reliable method for bedding and clothes, etc. Woollen clothes must be exposed to a dry heat of 180° or 200°, and this is best done in special ovens constructed for the purpose, now in possession of the local sanitary authorities.

Disinfection of the Patient. During the illness it is important to prevent discharges from the patient drying, and so being spread about as dust. All secretions, etc., are wiped away with moist swabs, which are put in some antiseptic solution. The mattress and pillow are protected by mackintosh or jaconette. After the patient has recovered, and before he mixes with his friends, he should have several warm baths and be rubbed with carbolic soap.

Disinfection of the Room. After the patient has left the room in which he has been ill it requires to be thoroughly disinfected before it is occupied by others. In most cases prolonged ventilation, with the scrubbing of the floor with soap and water, is sufficient. Articles that will not stand boiling may be often disinfected sufficiently by exposure to fresh air and sunlight. Where a gaseous disinfectant is required moist formalin vapour or sulphurous acid gas may be used.

In using formalin, a special apparatus (the Alformant lamp or Lingner's glycoformal apparatus) is required ; the room must be securely sealed and exposed to the vapour for at least four hours.

Sulphurous acid gas is obtained by burning sulphur. Three pounds of sulphur should be used for every 1,000 cubic feet of space in the room ; it is placed in one or more earthenware vessels or pipkins, and each should rest on two or three bricks in a large pan of water. The chinks of the windows should be pasted up with slips of brown paper ; the sulphur should be set alight, and the door should be closed and pasted up in the same way as the windows. After twenty-four hours the room may be entered, and the windows should be thrown wide open. Sulphur has the disadvantage of tarnishing metal work, and injuring pianos, sewing machines, etc., and these should be removed before the fumigation. After gaseous disinfection the wall paper should be stripped off and burned, the floor and woodwork thoroughly scrubbed with soap and water.

Notification of Infectious Diseases. The diseases specified for notification in the Infectious Disease (Notification) Act, 1889, are small-pox, cholera, diphtheria, membranous croup, erysipelas, scarlatina or scarlet fever, typhus, typhoid, enteric, relapsing, continued or puerperal fevers. The diseases generally notifiable under regulations of the Local Government Board and Ministry of Health are plague, cerebro-spinal fever, acute poliomyelitis, acute encephalitis lethargica, acute polioencephalitis, tuberculosis, ophthalmia neonatorum, dysentery, malaria (but not if induced for therapeutic reasons, unless patient is liable to relapse after discharge from hospital), acute primary pneumonia, acute influenzal pneumonia, and puerperal pyrexia. The following diseases are notifiable in particular districts either under (a) orders made by local authorities extending the Infectious Disease (Notification) Act, 1889, to the disease ; (b) local Acts ; or (c) special regulations made by the Minister : anthrax, glanders and hydrophobia, chicken-pox, whooping-cough, epidemic or summer diarrhoea of infants or zymotic enteritis, measles and German measles, pemphigus neonatorum, acute rheumatism in children under sixteen.

Immunity. Persons who are insusceptible to a particular disease are said to be immune.

Acquired immunity is that which is imparted in one or more ways to individuals previously susceptible. The most common cause of immunity towards an infectious disease is the fact that the individual has already had the disease. There are relatively few exceptions to the rule that scarlet fever, small-pox, chicken-pox, measles, and other such illnesses do not occur a second time in the same patient.

In contradistinction to this accidentally acquired immunity is *artificial immunity*, or the immunity intentionally or purposely acquired by the inoculation of the individual with some substance related to the virus or micro-organism which causes the disease. Artificial immunity may be *active* or *passive*.

In *active immunity* the body cells or fluids are themselves stimulated by the inoculation to the production of substances which will neutralise the injecting agent or its toxins. The substance injected may be the micro-organisms in *living culture*, weakened in virulence or *attenuated* ; or it may be the same micro-organisms in their full virulence, but in very small amount ; or it may be the dead organisms ; or it may be the bacterial products or toxins of the disease without the organisms.

In *passive* or *indirect immunity* the neutralising, and therefore protecting, substance is not provided by the body cells or fluids, but is supplied from without. In diphtheria, for example, a susceptible animal, for instance the horse, is gradually rendered immune by successive injections of increasing quantities of the culture fluid of the diphtheria bacillus, which contains the toxins but not the organism itself. When the animal is at length completely insusceptible, its blood serum is found to have the power of neutralising the influence of diphtheria cultures inoculated into animals ; and hence this serum contains a substance (*anti-toxin*) which antagonises the toxin of the diphtheria bacillus. The serum is standardised by experiment upon animals. The unit adopted by Ehrlich is the

amount which, when mixed with a hundred times the fatal dose of toxin, protects a guinea-pig of 250 grammes weight from death within four days.

If on the other hand the animal has been rendered immune by injections of certain bacteria, it is *antibacterial* or *antimicrobial*. In either case the effect of the injection has been to produce *anti-substances* in the horse's serum which operate in the blood of the animal (man) to be protected; and the materials injected for the purpose of modifying the serum are therefore called *antigens*. *Antitoxic sera* have been employed as cures; that is, the serum of immunised animals has been injected in order to neutralise the toxins of organisms already in the body, and causing symptoms (*serum therapeutics*), as, for instance, in diphtheria, tetanus and pneumonia. Specific antivenenes against venomous snakes are prepared by immunising horses with the venom, and when given intravenously often save life. The viperine antivenenes are also injected locally in the vicinity of the bite.

An important factor in protection from bacterial invasion is the process known as *phagocytosis*, or the destruction of the bacteria by the leucocytes and other cells of the body. The chief *phagocytes* are the monocytes and polymorphonuclear leucocytes, endothelial cells, and some tissue cells; they are attracted to the bacilli, and this attraction is called *chemiotaxis*. Polymorphonuclear leucocytes and eosinophils are classed as *microphages*; monocytes, endothelial cells, connective tissue cells, and other large cells are classed as *macrophages*. The former are more powerful in dealing with the bacteria of acute disease, the latter with those of chronic infections.

Anti-bodies. It has been shown that the entrance into the body of toxins, whether contained in the bacteria (*endotoxins*) or produced from bacteria (*exotoxins*), will cause the formation of *antitoxins*. This is only one instance of a large group of similar occurrences, for the injection not only of bacteria and toxins, but of cells, blood corpuscles, ferments, and other bodies, will cause the formation of *anti-bodies* or *anti-substances*—that is, of substances which act adversely to, and destroy, the bacteria, cells, and other substances which have been injected. The anti-bodies which result from infection are formed in the spleen, lymph glands, and bone marrow, by leucocytes or by endothelial cells, or by both.

Agglutinins form another group of anti-substances the development of which is stimulated by bacterial infection, or even by injection of the red corpuscles of another animal (*hæmagglutinins*). If in certain diseases (enteric fever, Mediterranean fever, dysentery, cholera) the blood serum of a patient or convalescent is mixed with cultures of the organism of the same disease, in a short time the bacilli are seen under the microscope to lose all active movements, and to become densely aggregated together (*agglutination*, or *clumping*). The same effect may be obvious to the naked eye if the serum and a culture fluid be mixed in a test-tube, when after a time precipitation of the bacilli takes place, leaving the upper part of the fluid clear (*sedimentation*). These facts form the basis of the diagnostic method known as *Widal's test* (see Enteric Fever). The action of agglutinins is not absolutely specific. Thus the typhoid agglutinin will clump not only the *Bacillus typhosus*, but also the paratyphoid bacilli and the *Bacillus coli*. The results vary with the time employed and with the extent of dilution of the serum. Agglutinins may also be obtained artificially, for the blood of an animal inoculated with sublethal doses of a given bacillus will acquire *agglutinative* properties towards the bacillus which has been injected (Bordet-Durham reaction).

Precipitins are similar substances, developed in the serum of animals which have been inoculated with bacterial culture fluids, albumose, milk, etc. The serum containing them precipitates the corresponding culture fluid, or a solution of the corresponding organic substance which has been used for inoculation.

The actions of *anti-bodies* in regard to bacteria, blood corpuscles, leucocytes, kidney cells, and other animal cells are known as *bacteriolysis*, *hæmolysis*, or *cytolysis*. They are for the most part specific; that is, if certain bacteria are inoculated into an animal the serum subsequently has a destructive

effect on the same kind of bacteria only; if rabbit's blood corpuscles are injected into a guinea-pig, the guinea-pig's serum will afterwards dissolve (or lysis) rabbit's blood outside the body; if liver cells are inoculated, the serum will dissolve liver cells, and so on. These different forms of cytolysis and hæmolysis are dependent not only upon the anti-body produced in the process (also known as *immune body*), but they also require the assistance of an enzyme which exists normally in the serum, and has been called the *complement*. Its presence is shown by the fact that the blood-dissolving power of a hæmolytic guinea-pig's serum may be neutralised by a temperature of 55° to 60° C., which destroys the complement; but it can be restored by the addition of serum from a healthy guinea-pig. The complement is probably a product of the leucocyte, and is identical with the *cytase* of Metchnikoff and the *alexine* of Buchner.

The facts connected with hæmolysis and the action of the complement are utilised in some important diagnostic methods (see Syphilis).

Another element in the protective power of the blood is the existence of *opsonins*, bodies which act on the bacteria so that they are more readily digested by the leucocytes (*opsono*, I cater for, or prepare food). The opsonic power of the serum is measured by the number of bacilli which the phagocytic leucocytes can take up (Wright and Douglas).

Anaphylaxis. In close relation to immunity and the operation of toxins are the phenomena known under the name of *anaphylaxis*, or *supersensitiveness*. This was discovered by Richet in 1902. He had injected a dog with a small dose of a poisonous protein from a sea-anemone, with the production of evanescent symptoms. Some weeks later he injected a second dose, expecting to find that some degree of immunity had been established, but instead there was a violent intoxication, and the dog succumbed. The name "anaphylaxis" means the opposite of immunity or "phylaxis." The explanation is as follows: Any foreign protein (antigen) injected into an animal causes the production of anti-bodies, which have the nature of *precipitins*. While these remain in the blood they produce immunity by precipitating further doses of the antigen. But after a time they largely disappear from the blood and enter the tissues. At this stage there will not be enough anti-body in the blood to precipitate the antigen, if injected, and so the latter will invade the tissues; but here the meeting of the two produces a violent reaction, viz. anaphylactic shock (1). This is proved by making an animal anaphylactic to horse serum, removing its uterus, washing it carefully free from blood and treating it with horse serum. A maximal contraction is obtained; but the uterus does not contract if other sera are used instead of horse serum. The reaction is thus specific. From what has been said it follows that though the animal shortly after an injection of antigen is not anaphylactic, its blood as soon as it contains anti-bodies is potentially anaphylactic, and if this blood is injected into a second animal the latter becomes passively anaphylactic or passively sensitised fifteen to eighteen hours later when the injected anti-body reaches the tissue cells. Further, it has been shown that the anti-body disappears from the blood *pari passu* as the animal becomes passively anaphylactic. Again, an animal may be treated with successive doses of antigen at frequent short intervals, so that the blood becomes crowded with anti-bodies and a high degree of active immunity is produced. Such an animal will not suffer from anaphylactic shock if a fresh dose of antigen is administered because there are sufficient anti-bodies in the blood to neutralise the antigen, although it may be proved that the tissues themselves also contain anti-bodies. It is this method that is used when a patient with hay fever is treated with small but gradually increasing doses of pollen, so that when subject to a large dose in the hay fever season no attack follows. There is another method of arresting anaphylaxis when it is once established. It is to give the animal a non-fatal anaphylactic shock which automatically gets rid of the anti-bodies from the

tissues, so that a refractory period of some duration follows before the anti-bodies become again stored in the tissues. This refractory state has been called anti-anaphylaxis.

Anaphylactic shock is always attended by more or less collapse of the animal, with fall of body temperature : but the main symptoms vary in different animals. Thus in the guinea-pig violent respiratory efforts are seen, and the smooth muscles of the bronchioles are found to be in extreme contraction. In the rabbit respirations are increased and death is due to right-sided heart failure, the result of increased resistance in the pulmonary circuit due to constriction of the pulmonary arterioles. In the dog the liver becomes greatly engorged. It is of interest to observe that there is a very great similarity between these reactions and those due to poisoning these animals by histamine. This suggests that it is the sudden breakdown of protein molecules with liberation of toxic amino-acids that is directly responsible for anaphylactic shock, a breakdown which is caused by the reaction of antigen and anti-body in the cells. The importance of anaphylaxis in relation to the clinical group of allergic diseases is dealt with on p. 138.

When an immunised serum is used for the treatment of diphtheria or other disease the patient sometimes (in about 7 per cent. of the cases) suffers from toxic symptoms, which develop in from seven to twelve days, and are due to the serum injected, and not to the anti-bodies in it. They consist of urticarial swelling at the site of injection, with swelling of the associated lymphatic glands ; spread of the eruption—urticarial, circinate, morbilliform or scarlatiniform—to the rest of the body ; glandular swelling in other parts ; œdema of the face, body or glottis ; pains in the joints ; slight pyrexia ; and occasionally albuminuria, jaundice, diarrhœa or bronchitis. Leucopenia of the polymorphonuclear cells also occurs following a leucocytosis in the stage of incubation. This is known as "serum disease." The symptoms pass off in a day or two. It has been suggested that serum disease is a true anaphylactic phenomenon, the antigen being present in sufficient amount not only to produce anti-bodies which enter the cells, but to enter the cells itself, with resulting anaphylactic shock.

Symptoms similar to those of serum disease are still more likely to occur after a second injection of serum, and are then certainly anaphylactic. The anaphylaxis requires from six to twelve days for its development ; hence a second injection before the period of six days usually produces no result. If the interval between the two injections is from twelve days to six or eight weeks (sometimes six months), two types of reaction may occur : (1) the *immediate reaction*, in which symptoms occur *shortly after* the second injection or within twenty-four hours, and pass off quickly, the general symptoms in twenty-four hours, the local in two or three days. These symptoms are œdema at the site of injection, pyrexia, swelling of glands, urticaria, œdema of the face and leucopenia. Occasionally serious symptoms (so-called *anaphylactic shock*) may occur within half an hour of the injection. The patient complains of difficulty in breathing, the chest becomes expanded and rigid, the face becomes congested, and the mucous membranes are cyanosed. Relief comes in from fifteen to thirty minutes. Patients have died in the attack. (2) The *accelerated reaction*, which comes on four to eight days after the second injection. It is called *accelerated* because it comes on sooner than the symptoms which follow a *single* injection. The symptoms are similar to those which occur after a single large dose (serum disease), but are generally more acute, passing off in twelve to eighteen hours.

The danger of the occurrence of anaphylactic shock should not prevent the administration of serum if it is indicated on therapeutic grounds. It is impossible to tell if a patient has become sensitised by a previous dose of serum ; but if it is thought that such may be the case, he must be *desensitised* if the second injection is made. The best plan is to inject $\frac{1}{2}$ or 1 c.c. of the serum five or six hours before the chief injection is to be made. If greater rapidity is desirable,

such a preliminary injection may be followed in five or ten minutes by a rather larger one, and so on at similar intervals with increasing doses until the whole has been given. The treatment of anaphylactic shock consists in intravenous or intramuscular injections of pituitary extract, atropine or adrenin, while pure oxygen is also administered in a rapid stream through a mask or funnel held as close as possible to the patient's face. Chloral hydrate may also be given.

The *Prausnitz-Küstner reaction* depends on a local passive sensitisation. The serum of an egg-sensitive person, for example, is injected intradermally into a normal person. Then if the normal person eats an egg a wheal appears at the site of injection, or this occurs if a dilute solution of egg is injected at the site.

PYREXIA

The terms *fever* and *pyrexia* are not always used in the same sense, *pyrexia* being sometimes limited to the mere fact that the body temperature is elevated, while by *fever* is understood the rise of temperature together with all the other bodily disturbances which usually accompany it.

Registration of Temperature. The temperature of the body is taken for ordinary clinical purposes by means of the clinical mercurial thermometer, which is a "maximum" thermometer. The bulb of the instrument may be placed in the axilla, the groin, the mouth, or the rectum.

In the two former situations it is necessary to see that there is complete contact of the skin with the bulb, and it must remain there sufficiently long for the surface of the skin to attain the temperature of the body generally; from one to three or five minutes suffice, according to the sensitiveness of the thermometer. In the mouth the bulb should be placed under the tongue, and the stem must be grasped by the lips. When the rectal temperature is taken, the bulb is introduced for $1\frac{1}{2}$ inches. The result can be depended on, but it is obviously a method that is not always convenient.

Range of Temperature. In health, with the subject at rest in bed, the *mouth* temperature varies from about 97° F. in the early morning up to 98.4° F. in the middle of the afternoon. The *rectal* temperature varies between about 98° and 99.5° F. under the same conditions. Muscular exercise may raise the rectal temperature by 2° F., while the mouth temperature remains the same or actually becomes lower. This is because the sweating and increased respiration tend to cool the mouth. The rectal temperature, on the other hand, approximates more closely to the internal temperature of the body. The temperature of the urine as discharged from the meatus is always slightly above the rectal temperature. The temperature of the axilla is about the same as that of the mouth, being somewhere intermediate between the skin and body temperature.

In a pyrexial disease the temperature ranges from 93.3° (35.5° C.), or even lower, to 110° or 111° (43.8° C.). Temperatures of 116° and 122° have been recorded, but considerable doubt attaches to their genuineness. The temperature is usually lower in the morning and higher in the evening; the lowest point is commonly reached about midnight or 2 A.M., and the highest from 4 to 6 P.M. It may be *continuous*, *remittent*, or *intermittent* as shown in Fig. 1. Occasionally the reverse obtains: the temperature is highest in the morning, lowest in the evening—*typus inversus*. The pulse and respiration rise and fall with the temperature, and the general discomfort of the patient varies in the same manner.

Pathology. The maintenance of the temperature of the body at its normal standard is dependent upon two factors, *Heat production* or *Thermogenesis* and *Heat loss* or *Thermolysis*. In fever there is increased heat production; this shows itself in the fact that the respiratory exchange (intake of O_2 and output of CO_2) is increased. During a malarial rigor the heat production has been found to

increase by 200 per cent., while the heat loss remains the same. During this time, about an hour perhaps, the body temperature is rising. When the high temperature is established the heat production falls to about 80 per cent. above normal, while the heat loss increases to cause a balance. In other fevers, unaccompanied by rigor, during the rise of temperature, both the heat production and heat loss rise step by step, the former being, of course, greater than the latter. When a high temperature is established, the heat production depends on the temperature and is about the same for all fevers, increasing by 7.2 per cent. for each degree F. Curiously enough, the amount of the rise is about the same as that of chemical reactions *in vitro* (4). The regulation of temperature is a probable function of the central nervous system as shown by the excessively high or low temperatures that may occur in some diseases of the brain and spinal cord, but it is also a function of the thyroid-adrenal apparatus. Heat production takes place in the organs of the body, particularly the skeletal muscles (*see Diseases of Thyroid and of Suprarenal Capsules*). Heat loss occurs to the extent of 87 per cent. from the skin by radiation, convection, conduction, and evaporation, to the extent of about 10 per cent. from the lungs, and to the extent of about 2 per cent. from the urine and faeces. The nerve apparatus concerned is chiefly the vasomotor system, by which the circulation through the skin is affected. If the

FIG. 1.—Types of Pyrexia.

skin becomes hot, the vessels dilate, so that the warm blood comes to the surface of the body. Sweating enormously increases the heat loss owing to the evaporation that occurs. With high fever respiration is quickened, and the loss of heat from the pulmonary surface is proportionately increased. A common result of pyrexia is a wastage of the body tissues, with increased nitrogen excretion in the urine. This may be partly due to the poisonous action of toxins on the body cells; but the nitrogen loss can be largely prevented by administering sufficient amounts of non-nitrogenous foods, especially carbohydrates. The body can then utilise these and so spare its own proteins. A high body temperature artificially produced in a normal subject does not cause a breakdown of body proteins if there are sufficient non-nitrogenous foodstuffs available (5).

Morbid Anatomy. Certain anatomical changes, probably chiefly due to bacterial infection, are common to nearly all deaths in high fever. The red corpuscles are diminished, and leucocytosis is common. Small petechiæ or hæmorrhages are found under the serous membranes of the pleura and pericardium. The solid organs—liver, spleen, and kidneys—are large and soft, and the kidneys and liver show, under the microscope, cloudy swelling with some granular change or fatty degeneration in their secreting cells. In hyperpyrexia the cells of the central nervous system stain diffusely, and Nissl's granules are absent. The lipoids in the cortex of the suprarenals are discharged.

The muscles may be soft and friable, or may show the degeneration which was first described by Zenker, and is now regarded as a coagulative necrosis. In this condition the muscular fibres are converted into a homogeneous, colourless, waxy-looking material, forming cylinders, which break up into fragments, and finally crumble into a granular detritus; it is sometimes accompanied by hæmorrhage. This change is most common in the abductors of the thighs, in the recti abdominis, in the diaphragm, and in the muscles of the tongue.

Symptoms. Pyrexia or fever is accompanied by many other disturbances besides elevation of temperature. These are in part a direct result of the high temperature; but in all cases of its production by disease toxins are circulating in the body, and they are probably the cause of certain disturbances.

Skin. It is hot to the touch, sometimes intensely so, and generally dry, but it may be moist, usually when the temperature is falling. In some diseases profuse sweats may occur, which sometimes perceptibly, sometimes scarcely at all, reduce the temperature. Such perspirations may cause an eruption of sudamina or miliaria. The colour of the skin over the body is generally normal, unless there are eruptions, such as miliaria, or the specific rashes of scarlatina, measles, typhus, and others. But the face is often flushed especially at the commencement of a fever; often the cheeks and lips are flushed, and the face is elsewhere pale; later on, with a failing circulation, the face becomes deeply congested or livid, and the extremities show the same change. The petechiæ and subcutaneous hæmorrhages which occur in the most malignant forms of infectious disorder (small-pox, typhus, measles, scarlatina) result, no doubt, from the action of virulent toxins upon the capillary walls.

Alimentary System. The tongue becomes furred; generally at first the fur is white, and the tongue is still moist; then the tongue becomes dry: the fur peels from the edges or tip, and shows the bright red tongue beneath. Later on the tongue becomes very dry, stiff, hard, dirty brown in colour, fissured on the surface, and caked with dried remains of saliva, food, and sometimes blood mixed with epithelium, which are allowed to accumulate in the passive state of the organs of mastication. In this stage also the gums are covered with a similar collection, which is called *sordes*. Loss of appetite, or anorexia, is one of the first signs of fever; sometimes sickness is present, and in all cases digestion is feeble. The bowels are usually constipated. The spleen is often slightly, in certain diseases very much, enlarged and tender.

Circulation. The heart's action is quickened, at first excited, then feebler. The pulse ranges from eighty to 120 or more. It is at first full, bounding and firm; it soon becomes softer and dicrotic. In later stages, as the heart becomes more feeble, it is quick, very small, very compressible, running or flickering.

Respiration. This is quickened in proportion to the pulse and the rise of temperature; it may rise to thirty or forty in the minute. When the illness has lasted some time, the bases of the lungs become congested (hypostatic congestion).

Kidneys. In consequence of the loss of aqueous vapour through the skin and lungs the urine in fever is scanty; and, as a direct result of this, it is high-coloured and deposits a brick-red sediment of urates on cooling. In severe febrile illnesses there may be a small quantity of albumin.

Nervous System. Headache is common at the commencement of pyrexia; there is also a heavy feeling, dulness, or disinclination to think or make any mental effort; after a time the patient not only does not wish to, but cannot, exert the intellect; he becomes drowsy, and when he drops off to sleep, begins to talk. Later on he is delirious without really sleeping, and the delirium may be muttering, and is occasionally maniacal, the patient getting out of bed, struggling with his nurses or attendants, or jumping out of the window. In the last stages there is profound unconsciousness or coma. In the earlier stage of coma the patient frequently picks with his fingers at the bedclothes, or catches

at imaginary objects in the air in front of him. The disturbance of the muscular system shows itself in general bodily weakness, tremor of tongue or limbs when they are moved, and twitching of the muscles (*subsultus tendinum*), while the relaxation of the sphincter ani allows the uncontrolled passage (incontinence) of fæces, and the diminished visceral sensations lead to retention of urine and dangerous distension of the bladder.

Course of Pyrexia. In many cases of fever a very definite course may be recognised. The rise of temperature at the beginning may be entirely unnoticed; but often there is a sensation of cold—it may be a mere chilly feeling, or he shivers, and finally he may have a definite *rigor*. This is an attack of shivering, in which the patient trembles all over, his teeth chatter, he feels intensely cold, his face is pinched, and the nose, ears and finger tips are livid. But though the surface is cold, the internal parts are hot, and the thermometer will show that the temperature is constantly rising from the first. The rigor may last from a few minutes to half an hour, an hour, or more. In young children rigors do not generally occur, but their place is sometimes taken by a convulsion. The second stage of the fever is the *fastigium*, in which the skin is hot and the various phenomena already recorded are present. The third stage is that of *defervescence* or decline, which occurs either by *crisis* or *lysis*. In *crisis* there is a rapid fall of temperature to the normal within twelve to thirty-six hours; it is sometimes accompanied by profuse sweating, sometimes by diarrhœa (critical sweat or diarrhœa). In *lysis* the temperature falls more slowly, taking three or four days to reach normal. For some days after a pyrexia the temperature may be unusually low (subnormal), *e.g.* 97° or 96° in the morning, and from this time the period of *convalescence* commences. Rigor, fastigium, and crisis occur typically in some forms of malaria, and may then all be completed within a period of six to twelve hours.

Prolonged Pyrexia. While we recognise that the duration of a pyrexia is determined mostly by the infection with which it is associated, and may therefore be from a few hours to several months, it may be useful here to mention the diseases which are most commonly found to be the causes of a pyrexia prolonged for several weeks or months. They are the following: typhoid and paratyphoid fevers, undulant fever, malarial fevers, kala-azar, trypanosomiasis, amœbic abscess of the liver, tuberculosis, septicæmia, pyelonephritis, malignant endocarditis, pernicious anæmia, leukæmia. Among less common conditions are syphilis, cirrhosis of the liver, Hodgkin's disease and malignant growths.

Subnormal Temperatures. The subject of abnormally low temperatures cannot properly be separated from the consideration of pyrexia, and the following list of the causes of subnormal temperatures may be found useful: (1) Direct withdrawal of heat from the body, as in case of exposure of unconscious or drunken persons in very cold atmospheres, or of immersion in very cold water. (2) Loss of great quantities of fluid from the body, as in severe diarrhœa, cholera, enteritis, or profuse hæmorrhage. (3) Conditions of cachexia and inanition, such as carcinoma of the various parts of the alimentary canal, severe diabetes, pernicious anæmia, convalescence from febrile affections, and many chronic mental diseases. (4) Various diseases of the central nervous system, the onset of cerebral hæmorrhage and embolism, some cases of cerebral tumour, and general paralysis of the insane. (5) The shock that may follow intestinal strangulation, perforations of the intestine, and surgical operations. (6) Extensive skin affections, such as universal eczema, and large burns. (7) Poisoning by phosphorus, atropine, morphine, carbolic acid, and alcohol; uræmia and diabetic coma.

General Treatment of Diseases attended with Pyrexia. The treatment will vary with the cause, and the length of the fever. The following applies particularly to a long case. The patient should be at absolute rest in bed, in a thoroughly ventilated, plainly furnished apartment, from which all hangings,

mirrors, striking pictures, or other objects likely to excite him in the event of his becoming delirious have been removed. The bed pan and urine bottle should be used so as to avoid exertion. He should be watched day and night, preferably by trained nurses, and should be kept scrupulously clean by sponging with tepid water daily. He should also be kept cool, the amount of clothes being lessened if the fever is very high. A distinct lowering of temperature may be sometimes effected in this way, a point to be remembered all the more as the tendency of the patient's friends is to heap clothes upon him to prevent his "catching cold." The extremities, however, must be carefully watched, and specially covered or warmed if necessary.

At the present day there is not the same tendency as previously to restrict the amount of food allowed the patient. Pyrexia is associated with increased metabolism, so that 2,000 calories or more may be allowed an adult if the pyrexia is long continued. It is essential that the diet should be easily digested, and it should be to the liking of the patient. It should be given in rather small amounts at frequent intervals, six to eight times in the day. Milk (2 or 3 pints in the day) will form an important element in the diet, and lactose, sugar or extract of malt may be added, so as to increase the calorie value. In cases where milk disagrees, or is felt to load the stomach, or is rejected, it may be citrated (sod. cit. gr. ii to 1 oz.), mixed with half its bulk, or an equal quantity, of barley water or soda water; or it may be peptonised or predigested by warming for a little time with liquor pancreaticus. Plenty of fluid should be taken—water, lemonade, weak tea, barley water, also toast water, etc., and to many of these sugar may be added. Arrowroot, cornflour, blanc-mange, custards, junkets, milk puddings, mashed potatoes and other vegetables, bread and butter, milk chocolate, eggs raw or lightly scrambled, may be allowed, and fish and minced chicken if the patient can tolerate them. Fruit, fresh and stewed, *e.g.* apples, grapes, plums, are often much appreciated; but pips, skins and excessive fibre should be avoided; this can be done in the case of oranges, raspberries, currants, etc., by giving the fruit juice. It must be remembered that beef tea, mutton broth, chicken broth, and veal broth, although they may act excellently in stimulating the appetite, have practically no value as foods.

Frequent attention to the mouth is necessary, since the accumulation therein of secretions and sordes is likely to be followed by parotitis and other complications. The mouth should be washed out after each feeding, or more frequently, according to the amount of the secretions, with an antiseptic solution, such as a solution of thymol in water or 2 per cent. boric acid.

When the intensity of the toxæmia reaches a certain point, and the patient's organic sensations are dulled, the bladder should be carefully watched, to provide against retention of urine. Fulness and dullness on percussion above the pubes are the signs of a full bladder, and the mere statement of the attendants that the patient is passing his urine must not be accepted as a proof that no urine is being retained. The frequent involuntary discharge of small quantities of urine is, indeed, the result of the bladder being already distended; and even the discharge of larger quantities at the request of the nurse may still leave a pint or more in the bladder, which will be revealed on manual examination. The catheter must be kept in place as long as the disability persists. Care must be taken to prevent bed-sores.

In some cases of pyrexia the temperature has been directly dealt with by methods known as *antipyretic*. It must be distinctly understood that such treatment will not lessen the duration of the illness; that in many illnesses the temperature will of itself fall in a few hours, that is, in the early morning; that in temperate climates there is very rarely any danger that it will rise to a height which can be directly fatal; and that any considerable lowering of the temperature by artificial means falsifies to a certain extent the information which the temperature gives to the physician as to the course of the disease. But most

important of all, pyrexia is to be looked upon as a defensive mechanism on the part of the body against the infecting micro-organisms, and hence it should not be interfered with without careful consideration. However, it is possible to have too much of a good thing, and in very long continued fever, such as typhoid, the pyrexia may eventually act deleteriously on nerve cells and other tissues, so that the application of external cold in the form of baths not only often increases the comfort of the patient during the time that each successive dose or application is in operation, but diminishes the headache, delirium, or stupor and improves the pulse. It is claimed that the mortality of typhoid has been improved by 5 or 6 per cent. by such means. Care must be taken to avoid collapse of the patient.

Antipyretic methods may be divided into three groups :

Milder Refrigerants. These are the ordinary saline remedies—citrate of potassium (10 to 30 grains), liq. ammonii acetatis ($\frac{1}{2}$ ounce), dilute acids—which were formerly given in every fever, but have very little influence.

Stronger Antipyretic Drugs. These drugs are very little employed at the present time for their purely antipyretic action. If one of them is given in a single dose to a patient with a temperature of 103° or 104° , the temperature falls within two or three hours to normal or even lower, but it rises again in six or seven hours to a height not much different, if at all, from what it would have reached had no antipyretic been given. The following have been most often employed: quinine sulphate, 20 to 30 grains; salicin, 30 grains; salicylic acid, 20 grains; antipyrin (phenazone), 15 grains; antifebrin (acetanilide), 2 to 5 grains; phenacetin, 5 to 10 grains. The last three are the most certain in their antipyretic action, but in doses beyond the limit stated these drugs are apt, especially the last two, to cause alarming cyanosis and collapse.

External Application of Cold. This may be done in several ways: the cold bath; the wet pack; sponging; ice applications; Leiter's coils. Though more troublesome than the administration of drugs, its use can be better controlled, and there is less risk of harm to the patient.

Hydrotherapy. This has been largely used in the treatment of enteric fever. The temperature is taken every three hours, and whenever it is found at any of these periodical observations to be 102° F. or higher, the patient is placed in a bath of a temperature of 70° F., in which he remains for ten or fifteen minutes, according to its effect upon him. He is then removed, lightly dried, and replaced in bed. The temperature will then be generally found to have fallen to 99° , 98° , or even lower. The system is open to modifications: the observations may be made less frequently, the bath may be only used when the body heat is 102.5° , or 103° , or 103.5° , and the temperature of the bath may be as low as 60° or as high as 80° or 90° . Sometimes the patient is put in the bath at a temperature of 90° , and ice is then introduced to bring down the heat to 75° or 70° . It is obvious that the greater the number of baths, and the lower their temperature, the greater will be their effect upon the mean body heat. Continuous immersion has been also successfully employed.

Wet Pack. A sheet is wrung out of ice-cold water and wrapped round the patient for ten or fifteen minutes, the application being made under the same conditions of bodily temperature as are directed for the bath.

Sponging. The body is uncovered and sponged over with cold or ice-cold water for from seven to ten or fifteen minutes. This method is not generally so effective as the two former; the temperature commonly falls from one and a half to two degrees.

Ice-bags. These may be placed on the chest or abdomen for varying periods, or hung within a cradle placed over the patient. The application of an ice-bag to the head is often a good method of relieving headache.

Stimulants. In all febrile illnesses a stage may be reached when the heart's action and the nervous system are so profoundly affected that some kind

of artificial stimulation is required ; but although the signs indicative of such a stage are, as a rule, severe in proportion to the elevation of the temperature, they are due not so much to the fever itself as to the toxins which circulate in the blood, and are themselves the cause of the pyrexia. The results of such cardiac failure and nervous prostration are quick and feeble pulse, inaudible first sound of the heart, irregular action of the heart, cyanosis, congestion and œdema of the bases of the lungs, dry tremulous tongue, muscular tremor, sleeplessness, and delirium.

The simplest method of stimulation, and one long in vogue, is the administration of alcohol in the form of brandy or whisky ; the quantity may be from 2 to 6 or 8 ounces in the twenty-four hours. But the larger amounts must not be continued for many days ; and especially in prolonged illnesses, like typhoid fever, the effects of this drug must be carefully watched, since an excessive amount will keep up a quick pulse and a drowsy muttering delirium, deceptively like the very condition for which it was originally given. If the delirium assumes a maniacal form, it is very likely to be aggravated by alcohol.

In more recent times there has been an increasing tendency to prefer other modes of stimulation, which may often be used with success. Such are the following : the internal administration of spirit ammon. aromat. in doses of 30 minims or tincture of digitalis 15 or 20 minims three times a day ; the intramuscular injection of the double salt of caffein and sodium salicylate or of caffein and sodium benzoate in the dose of 5 grains for an adult ; the intramuscular injection of camphor in 10 or 15 or 20 per cent. solution in olive oil (or oil of sesame), the dose of camphor for an adult being from 3 to 5 grains ; the intramuscular injection of adrenalin (5 to 10 minims of the 1 in 1,000 solution). In any case the result of each dose will be the guide to the time at which the next should be given.

Insomnia. The following remarks are applicable generally, and not only to pyrexia.

There is now available a fairly wide variety of useful hypnotics. The principal hypnotics may be grouped as follows :

(1) Bromide salts, especially potassium and ammonium bromide (10 to 30 grains).

(2) Chloral hydrate (10 to 30 grains) and its ally, chloralamide or chloral formamide (10 to 60 grains).

(3) The barbituric acid group : Barbitone (veronal) (5 to 10 grains), medinal (sodium barbitone) (5 to 15 grains), dial ($1\frac{1}{2}$ grains), allonal (2 to 4 tablets), luminal (2 to 5 grains), etc.

(4) A group also derived from urea, but without a carbon ring in the nucleus : adalin and bromural (5 to 15 grains).

(5) The sulphone group : sulphonal (20 to 40 grains) and methylsulphonal (trional) (10 to 20 grains).

(6) Paraldehyde (1 to 2 drams).

(7) Hyoscine hydrobromide ($\frac{1}{100}$ grain).

(8) Opium and its derivatives, *e.g.*, morphia, heroin ($\frac{1}{5}$ to $\frac{1}{8}$ grain) and pantopon ($\frac{1}{8}$ to $\frac{1}{2}$ grain).

When sleeplessness is due to pain, an analgesic like aspirin (5 to 15 grains), pyramidon (5 to 8 grains) or veramon (5 grains) may be tried along with a dose of one of the first six groups. But the only effective hypnotics when there is much pain are opium or its derivatives. Opium may be given by mouth as Dover's powder (10 to 15 grains), or, if a more rapid effect is desired, subcutaneously as morphine ($\frac{1}{8}$ to $\frac{1}{2}$ grain). When insomnia complicates a febrile illness, a drug of the first six groups may be tried, and chloral or paraldehyde are in fact to be preferred to bromides or the barbituric or sulphone series, as the latter are apt to produce in these circumstances a certain amount of dulling and sometimes actual mental confusion, while not succeeding very well in producing sleep. In severe

prolonged febrile illness, such as a streptococcal septicæmia, morphine is the most satisfactory hypnotic.

In pneumonia, morphine is mainly used in the first five days, but after the fifth day is contra-indicated (respiratory depression), when paraldehyde may be substituted. A mixture of chloral and digitalis may be used instead from the beginning. In acute bronchitis, opium is usually contra-indicated; but when the sleeplessness is due to cough, and there is not too much secretion, morphine, heroin or dionin is permissible (and also in the insomnia from cough in chronic phthisis).

In the dyspnœa of heart disease, opium "acts like a charm" and so greatly promotes sleep. In other causes of insomnia in cardiac disease (apart from dyspnœa), chloral is valuable, and has not the dangerous depressant cardiac effect that it is alleged to have. Paraldehyde should however be used instead when myocardial degeneration is suspected.

In delirium, when chloral and paraldehyde have failed, and when there is much restlessness endangering the patient, hyoscine hydrobromide ($\frac{1}{100}$ grain) may be given hypodermically and repeated with care if necessary, but in smaller doses ($\frac{1}{50}$), and a second dose should not be given within two hours of the first.

In insomnia due to anxiety or other mental cause the barbituric acid group is particularly useful. These drugs have to be given with special care in elderly people in whom the tendency to a cumulative effect is greater. When these fail, and sleep is urgently required in mental conditions, chloral (often given with bromide) and paraldehyde may have to be resorted to. Continuous tub treatment, if properly given, may make hypnotics unnecessary, but it requires special equipment and a trained attendant. The cold wet pack for young, robust, excited patients, or a warm wet pack for excited patients of any age if in good physical condition, are especially valuable in insomnia associated with much restlessness in mental disorders.

The bromides are sedative rather than hypnotic, but may suffice in mild recent insomnia. They are also helpful if taken over a long period in the over-anxious individual. The cumulative action, including the tendency to produce acne, has to be watched.

Convalescence. After a short febrile attack, such as influenza, the patient may be allowed to get up after the temperature has been down for twenty-four hours. After long attacks the patient may be helped on to a couch for a few hours after the temperature has been down for two or three days. The time up is gradually increased. The next stage is to allow the patient to get up himself and to sit on a chair. After a week or ten days he may be allowed to walk about the room, then to go downstairs. Walking outdoors and climbing stairs may be allowed after two or three weeks. It is customary to prescribe a tonic during convalescence, such as iron or cod-liver oil, malt extract, or a mixture containing acid hydrochlor. dil. 10 minims, tr. nucis vom. 10 minims and Infus. gent. ad 1 oz. a.c.

Diseases caused by ultra-filterable viruses or of unknown origin.

MEASLES

(*Morbilli*)

Measles is a contagious febrile disease, characterised by an eruption of pink or red spots and catarrh of the respiratory mucous membranes.

Ætiology. In civilised communities its spread is determined by circumstances very similar to those influencing scarlatina. It occurs in epidemics, which attack the young rather than the old, chiefly because nearly all the older members of the community have had the disease when young, and are thereby protected from a second infection; but infants up to six months are either

insusceptible or get the disease in a mild form (48). In large towns it is almost continuously present, spreading from point to point in the form of limited outbreaks, which subside, and are succeeded by others in different places; but where introduced among populations that have never been visited by the disease, or have been entirely free from it for years, it attacks the majority of the people, young and old alike, in one great and often destructive epidemic. This was the case in the Faroe Islands in 1846.

Infection is due to an unknown virus which is present in the secretions from the nose and throat. Experimentally the disease has been transmitted by inoculation from this source. Infection is spread from inhalation of droplets of saliva projected into the air by talking and coughing during the catarrhal stage of the disease; the virus also adheres to clothes, toys and other articles, though with much less tenacity than does the contagion of scarlatina.

Morbid Anatomy. This depends on the complication causing death, since uncomplicated measles is so rarely fatal.

Symptoms and Course. The period of *incubation* in measles is usually eight to sixteen days (limits—six to twenty) (12). The disease commences with pyrexia and catarrhal symptoms: the temperature rises perhaps to 102° ; the child loses appetite, is drowsy and unwell; there may be at first vomiting or chills, or, in children, convulsions. With this the conjunctivæ becomes suffused; the eyes water; there is a mucous discharge from the nose, and cough as a result of bronchial secretion. The catarrhal symptoms continue, but the temperature frequently falls after the first day, and continues at a lower level for another day or two, when it again rises. Occasionally in this early period there is a so-called prodromal rash, which may be like that of scarlatina, or urticarial, or like the true measles rash. It lasts only twenty-four or thirty-six hours.

The characteristic eruption appears most commonly on the fourth day, but it may be as early as the third. It is first seen on the face, at the roots of the hair, on the forehead, temple, or behind the ears, and it subsequently spreads to the neck, trunk, and limbs. It consists of pink spots, round, oval, or irregularly shaped, slightly raised above the surface, running together into irregular groups, which may have a somewhat crescentic shape, and leave some intervening area of skin unaffected. In colour, it is generally darker red, or more purple than that of scarlatina; but a distinction may be difficult, especially if the spots are uniformly distributed and do not coalesce. Occasionally a few petechiæ occur in the darkest part of the eruption, and in other cases a few vesicles may form in the centres of some papules. It comes out most fully on the face, giving it a blotchy, swollen appearance, and though less abundant on the extremities, it may form continuous patches of infiltration on the back and arms. It takes from one to three days to reach its height, and then rapidly declines, mostly beginning to fade first where it first appeared. It commonly leaves some mottling of brown or yellowish-brown colour, which lasts for some days; while petechiæ leave still more pronounced stains. It is also succeeded by slight desquamation in minute branny scales, but never in the large flakes seen in scarlatina.

If the temperature has fallen in the prodromal stage, it rises again, with the appearance of the rash, to 102° , 103° , or even higher, and, reaching a maximum in two, three, or four days, falls generally rather suddenly as the rash begins to fade, and may reach the normal in about thirty-six hours. The catarrh continues throughout the eruptive stage; it may extend

FIG. 2. — Temperature in Measles. (After Strümpell.)

into the frontal sinuses and cause headache. There is more or less general bronchitis, indicated by cough, expectoration of mucus, and diffused rhonchi; and the larynx may be implicated, as shown by hoarseness, croupy cough, and in occasional cases by stridulous breathing. Even before the appearance of the rash the palate often shows abnormal redness, diffused or in patches, and almost invariably the lesions known as *Filatow's* or *Koplik's spots*. These are small, raised, white or opal dots, the size of a small pin's head, generally on a reddened base. They are seen best on the buccal mucous membrane opposite the premolar teeth of the lower jaw, and to a less extent opposite the other teeth. These appear two or three days before the eruption. The tongue is usually furred, and the fungiform papillæ are prominent. After the subsidence of the fever the return to normal appetite and sleep is generally rapid.

Complications and Sequelæ.¹ The most important complications are those connected with the respiratory organs, and it is to them that the majority of the deaths in connection with measles are due. Inflammation of the lungs is of frequent occurrence, and has generally been attributed to an extension of the bronchitis, which is common in all cases of the disease. But the pneumonia may be lobular or lobar in its distribution, and it may present in one case the features of a *broncho-pneumonia* (16·2), and in another case those of a lobar or pneumococcal pneumonia. The *laryngitis* (2·7) may be so severe as to threaten asphyxia, and may be accompanied with the formation of membrane; in some such cases it is a true diphtheria; in others it is caused by pyogenic organisms. Other complications are conjunctivitis (1·3), keratitis (·3) or iritis, stomatitis (1·7) and parotitis, inflammation of the Eustachian tube, *otitis* (8·3), diarrhœa or dysentery from enteritis of the small or large intestine respectively, albuminuria (3·3), and intestinal hæmorrhage. Gangrene of the mouth, called *cancrum oris*, or *noma*, occurs occasionally (·9), and gangrene of the vulva, also called *noma*, more rarely. The encephalitis of measles is described later.

Varieties. Measles without eruption and measles without catarrh have both been described; but it is doubtful if the former occurs, and some cases of the latter may really have been instances of rubella or German measles (*see* p. 27). In either case, the disease is mild. Of the severer or malignant forms *hæmorrhagic* measles is an example, in which bleeding takes place from mucous membranes, and the eruption becomes *purpuric*. Other severe forms are merely characterised by intense fever, dark or livid rash, often imperfectly developed, rapid and feeble pulse, prostration, delirium, dry brown tongue, and a generally typhoid condition.

Diagnosis. A confusion with *scarlatina* and *rubella* is most likely to occur (*see* p. 27). In *typhus* the rash is not so papular, the face is but little affected, the spleen is swollen, and there is no nasal or conjunctival catarrh. The early stage of a *small-pox* eruption is sometimes simulated by that of measles; the absence of catarrh and the history of headache, back pain and sickness, are in favour of variola. Roseolous eruptions, apart from specific fevers, may resemble measles, but will be distinguished by the absence of the characteristic fever and catarrh. Koplik's spots are of value in diagnosis, as they rarely occur in other eruptive diseases.

Prognosis. This is usually favourable. For the most part the mortality is from 1 to 2 per cent., though occasionally epidemics of much greater severity have occurred; and the prevalence of pulmonary and laryngeal complications increases considerably the percentage of deaths. Apart from these, the malignant cases are recognised by intense fever, dark or livid eruptions, and early collapse or prostration.

Prevention. The only successful specific method of prevention is to inject serum taken from a convalescent patient seven to eleven days after the tempera-

¹ The bracketed figures in *italics* are percentages from 747 cases in the Metropolitan Asylums Board's hospitals in 1914. No later data have been published.

ture has become normal (48). The serum which is also tested by the Wassermann reaction can be stored in the cold for many months; 6 c.c. are used for children under three months and 6 to 10 c.c. for older children, and the injection should be made during the first five or six days of incubation to prevent an attack; if later, *i.e.* up to the ninth day, the attack will be less severe.

Treatment. The general treatment of pyrexia should be consulted. Confinement to bed is scarcely necessary till the eruption appears. The catarrh which is present from the first should be treated as described under Bronchitis. The treatment of the fauces and of otitis is the same as in scarlet fever; of the nose and larynx as in diphtheria. Broncho-pneumonia with cyanosis has been treated successfully with the oxygen tent.

RUBELLA

(*Roseola, Rötheln, German Measles*)

This is an exanthem, resembling in many points both measles and scarlatina, but undoubtedly distinct from both. No specific micro-organism has yet been discovered in connection with it.

Ætiology. It is not so infectious as measles, being spread in much the same way, especially by close association with some one suffering from the disease. Restricted outbreaks are a common result, older children and young adults being readily infected.

Symptoms. The period of *incubation* is nine to nineteen days. A prodromal stage is either entirely absent, or at most lasts half a day before the appearance of the eruption; and this stage may be represented by a slight catarrh of the mucous membranes of the air passages or of the conjunctiva. But in some cases the *eruption* is the first indication of anything wrong with the patient. It consists of a number of pink spots, round or oval, very slightly raised above the surface, uniformly scattered, and generally discrete, though sometimes very closely set. The spots vary in size; when small and closely set there may be much resemblance to a scarlatinal rash; when larger there is more likeness to measles, but they are not commonly confluent, and do not take any crescentic form. Slight itching of the skin may be experienced. The eruption occupies the face, trunk, arms, and legs, appearing mostly on the face first and rapidly occurring on the other parts; it is generally of shorter duration than measles, often lasting only two days, sometimes three or four. As in measles, it may leave a little discoloration of the skin for some days afterwards; desquamation is commonly absent, and it is never in large flakes, as in scarlatina. The palate and fauces usually show some injection or spots and streaks of redness, and the tonsils may be a little swollen. The conjunctivæ are reddened, and coughing and sneezing are generally present to a slight extent. The *lymphatic glands* at the back of the neck in the occipital mastoid and posterior cervical regions are frequently swollen and tender, and sometimes those in other parts of the body. The swelling may persist two or three weeks, but suppuration has never been observed. Fever is, in the majority of cases, entirely absent; if it occurs, the temperature is only 1.5° or 2° above the normal, and it lasts one, two, or at most three days, showing the greatest variability in different cases, but often falling to normal before the eruption is completely developed. Many patients do not feel ill at all, and retain their appetite throughout. Any further complications than those indicated already are quite uncommon, and the prognosis is exceedingly favourable.

Treatment. This must be conducted on the lines laid down for measles.

Differential Diagnosis of Scarlatina, Measles and Rubella. *Initial stage.* In scarlatina the onset is sudden, and the first stage lasts twenty-four hours. There are nausea and vomiting, but not much catarrh. In measles there

are definite catarrh and conjunctival suffusion for over three days before the rash. In rubella there is slight catarrh, which may last only a few hours.

Adenitis. In scarlatina the glands below the angles of the jaw are definitely affected and are sometimes palpable in other regions. In measles there may be slight swelling below the angles of the jaw; very occasionally the posterior glands are affected, as in rubella. In rubella there is characteristic enlargement of the glands at the back of the neck.

Nature of Rash. In scarlatina there are minute papules and a general erythema, often brick-red in colour. It may be patchy on the extremities. There may be some apparent swelling of the skin. In measles the spots are large and red and may form definite patches with curved outlines. In rubella the spots are smaller, rounder and pinker than in measles, and more discrete. Coalescence into patches may sometimes occur.

Distribution of Rash. In scarlatina the palms, soles, and face are reddened but not affected by the rash. There is marked circum-oral pallor. The scalp also escapes. In measles and rubella all parts may be affected, and the circum-oral region is very constantly invaded.

Fever. In scarlatina the pyrexia is marked and the pulse rapid; sore throat is prominent, and there is intense injection of the palate, and, except in the septic form, there is usually no bronchial catarrh. Defervescence is rather gradual. In measles the pyrexia is definite, and there is much constitutional disturbance, without a sore throat. Koplik spots are present in over 90 per cent. of cases on the buccal mucous membrane. Bronchial catarrh is a usual feature, often leading on to broncho-pneumonia. In rubella the pyrexia is slight and sometimes absent, and the patient feels well. Sore throat, if present, is very slight, and there is usually no bronchial catarrh.

Tongue. In scarlatina the tongue passes quickly through three stages:—furred with red edges, patchy, strawberry. In measles it may be well coated, and is occasionally patchy, but not typically strawberry. In rubella there may be slight furring.

Skin after Rash fades. In scarlatina the skin looks rather opaque, like parchment, and more or less sallow from pigment. Desquamation is of the pinhole-and-flake type; the pinholes are usually best seen at the outset on the neck. Desquamation is often very copious. In measles there is dirty brown mottling. Desquamation is fine, branny and not very copious. In rubella there may be faint yellowish-brown staining for a few days, but this is unusual. The desquamation is as a rule almost inappreciable.

SMALL-POX

(*Variola*)

Small-pox is a specific contagious disease, with a characteristic pustular eruption, due to a virus which is probably ultra-microscopic.

Ætiology. This disease arises solely by contagion, chiefly, no doubt, by inhalation of the atmosphere surrounding infected persons. When cases are aggregated in hospital infection by aerial convection is believed to occur for at least a quarter of a mile. It is also conveyed by clothes, bedding, and other things, which have been in contact with patients; and it can be inoculated by means of the contents of the pustules. But patients are infectious before the eruption, and the virus is given off even from the bodies of those who have died. The susceptibility to the disease is common to all ages and both sexes; even the foetus *in utero* may catch it from the mother; but the susceptibility then and in the first year of life is stated to be less than afterwards. The disease commonly occurs only once in the same individual; but second and third attacks

occasionally occur, and the second attack may even be more severe than the first, though it is generally milder.

The liability to the disease, and consequently the number and severity of its epidemics, have been reduced considerably since the introduction of vaccination at the end of the eighteenth century. For instance, in this country there were annually several thousand deaths from small-pox in the middle of the last century (2). In 1871, owing to infection introduced with refugees from Europe at the time of the Franco-Prussian War, the number of deaths amounted to 23,000; but since that time there has been a steady diminution, and since 1905 the number of deaths has always been under thirty. This favourable result cannot be due chiefly to vaccination, because the proportion of infants vaccinated to the number of births has decreased since the beginning of this century. It is due rather to increased facilities of diagnosis since the disease became notifiable, and also probably to the mild form of the disease in England at present.

Epidemics of small-pox vary in severity. The milder form is now called *Variola Minor*; it occurred originally as “*alastrim*” in Africa and America. The severer form of Asia and Europe is now called *Variola Major*. Both forms, on the whole, breed true to type, but they are the same disease, as is proved by immunity reactions.

Morbid Anatomy. In hæmorrhagic cases blood may be found effused into the solid viscera. Examination of the pustules shows that the process begins with hyperæmia of the papillary layer of the cutis; then the superficial layer of the cuticle is raised from the deeper layers to form a vesicle. The umbilication is sometimes determined by a hair, or the duct of a sweat gland preventing distension at this spot, or merely by cells of the rete Malpighi stretched into a fibre; bands and fibres formed in the same way constitute the septa dividing the vesicle into *loculi*. The pustule becomes hemispherical, in the later stages of suppuration, by the central band or *retinaculum* giving way. Whether the resulting scars are superficial or deep depends upon the extent to which the suppurative process involves the papillary layer of the skin. Micrococci due to secondary infections have been found in the pus and in various organs. The liver cells show fatty degeneration early in the disease.

Variola Major. The period of *incubation* is ten to fourteen days. The disease mostly begins suddenly with a distinct rigor or chills, with severe backache (lumbosacral pains), severe headache, vomiting and prostration. The temperature rises rapidly to 102°, 103°, or 104°, and the next day it may be still higher (Fig. 3). On the third day the typical eruption appears; but in the initial stage in a certain number of cases rashes occur, with which it is important for diagnostic purposes to be acquainted.

Early Eruptions. These are (1) *erythematous* and (2) *hæmorrhagic*.

(1) The erythematous rash tends to appear before the hæmorrhagic. In mild or modified small-pox it takes the form of irregularly shaped patches, which tend to be evanescent and migratory, and are not appreciably raised above the surface. It is often supposed to resemble measles, but rarely spreads any higher on to the face than the level of the lower jaw. In severe small-pox the erythema forms large areas, or plaques, of a brilliant colour, with well-defined margins on the external surfaces of the limbs and on the trunk. More rarely the whole body surface is covered with a continuous sheet of erythema, but this is not punctate like scarlet fever.

(2) The hæmorrhagic rashes indicate a more severe degree of infection. They have a special affinity for flexures and may begin as an erythema. One of the most characteristic is the “*triangular rash*,” which occupies the lower half of the abdomen, from the umbilicus downwards, covers the groins, and extends on to the thighs. It has the form of an inverted isosceles triangle, with the base about the level of the umbilicus. It also frequently appears in the axillæ, and on the adjacent parts of the arms and trunk, and extends thence along the flanks

to the lower patches. It consists of small hæmorrhagic spots, or petechiæ, which on fading leave brown or yellowish-brown stains for a time. These initial rashes commonly appear on the second day, and last for about two days, co-existing with the early stage of the papular eruption, but disappearing before its full development.

Another form of hæmorrhagic rash is the *purpura variolosa*, which constitutes a very severe variety of the disease. On the second day, or even within twenty-four hours of the first symptom, a scarlatiniform rash appears, quickly followed by subcutaneous hæmorrhage, partly petechial, partly in larger patches. The face is red and puffy, the eyes suffused; there may be vomiting of bilious matters or of blood, with the passage of bloody stools, and the urine contains albumin or blood. The mind is generally clear till near the end; exceptionally delirium or coma is observed. The cases are nearly always fatal, often within three days of the commencement, and even earlier.

Specific or Focal Eruption. This commonly begins on the third day of the illness by the formation of small red papules on the face, forehead, and scalp, and the same appear subsequently on the chest, back, arms, and hands, finally on the lower part of the body, the legs and feet. These papules soon become

FIG. 3.—Temperature in Small-pox. (After Strümpell.)

prominent; they are firm, and give to the finger the impression of extending deeply, a condition sometimes described as “shotty.” Towards the end of the second day of their appearance a small vesicle appears in the centre, which is at first clear and transparent. As it gets larger, during the next two days, a very characteristic change takes place: the centre becomes depressed, and the circumferential part forms a prominent ring round it. This process is known as the *umbilication* of the vesicle. If the vesicle be punctured, only a small quantity of the contained serum will escape, the retention of the remainder being due to septa which divide the vesicle into separate cavities or *loculi*. Almost coincidently with the umbilication of the vesicle, the contents become more opaque; and finally, about the sixth day (eighth of the disease), they are completely purulent. During this change in the vesicle the surrounding skin becomes pink, forming an inflammatory halo around it, and if there are many pustules—for instance, on the face—this leads to a great deal of swelling, which is often so considerable as to render recognition of the features quite impossible. The scalp becomes tense and tender, and the fingers also are often much swollen from the same cause. The stage of suppuration lasts two or three days, and then the pustules gradually dry up, beginning at the centre, and ultimately forming a brown or blackish-brown scab, which adheres for several days. Sometimes the desiccation is preceded by the escape of some pus from the vesicle, and with the drying up the swelling of the face and other parts subsides. Finally, the scab falls off, leaving a dark red spot,

which is at first slightly raised above the general surface, but in the course of some weeks forms a depressed white scar. The pustules form most abundantly on the face, and on the backs of the hands, and are less numerous on the trunk and covered parts of the limbs. Parts that have been the seat of initial erythematous or petechial rashes are by many said to be less liable to the specific eruption. All the stages of the eruption occur first on the face, and follow, a day or so later, on the trunk and extremities. On the other hand, parts which have been irritated, as, *e.g.*, by the application of plasters or blisters, are liable to an abundant formation of pustules. The pustules are not confined to the skin, but occur on the mucous membranes also; they are especially well seen in the mouth, on the hard and soft palate, but present different appearances from those on the skin on account of the constant moisture to which they are subject. They scarcely develop into well-formed pustules, but are only grey or pearly elevations, which are liable to become abraded and form superficial erosions or ulcers. The tongue is generally coated and more or less covered with pustules; rarely its substance is inflamed. Ulceration of the larynx or even perichondritis may occur; and the process may extend to the nasal mucous membrane, so that the breathing is obstructed by the swelling and the formation of scabs.

In mild cases the *primary fever* subsides with the appearance of the specific eruption (Fig. 3), and the temperature may become quite normal, so that patients who have remained at home during the first three days will go to their doctor or the hospital with an abundant crop of papules all over the body, but feeling comparatively well, free not only of the fever, but of the headache, lumbar pains, vomiting, and general malaise.

But when the pocks become purulent there is a fresh accession of fever, a *secondary* or *septic fever*, which may be ushered in by chills, or a rigor, and which lasts from three to six or eight days (Fig. 3). The temperature rises to 103° or 104°, is mostly remittent in its course, and is accompanied with sleeplessness, headache, and delirium, and a pulse of 100 to 120. All this again subsides as the scabs dry and the swelling of the skin decreases. With the fall of the scabs some patients lose their hair, and even their nails.

Confluent small-pox is a form in which the eruption is very abundant, and the general illness is correspondingly severe. The initial fever is high, and the temperature does not fall to normal with the appearance of the rash, as it does in mild cases. The rash appears early, even by the second day, and is very abundant, so that on the face, which is most affected, the pustules are closely set, the skin is enormously swollen, and in the stage of suppuration several pustules coalesce and form irregular and more or less extensive purulent blebs. The implication of the mucous membranes of the nose, throat and larynx is much more constant and severe. The secondary fever is also high, and is accompanied by prostration, rapid pulse, and delirium or coma. Complications are more frequent and serious, and the mortality is great, death taking place from exhaustion, or hyperpyrexia, or pyæmia.

Malignant small-pox, or *purpura variolosa*, in which hæmorrhages appear in the skin within the first forty-eight hours, has been mentioned; in another form the hæmorrhagic tendency shows itself later. The specific eruption appears, and then hæmorrhage takes place into the papules, or later still into the pustules, or into the skin between the pustules. The petechiæ often occur first on the lower extremities. The mucous membranes are also affected with hæmorrhages, or membranous patches, and bleeding occurs from the nose, lungs, rectum, kidneys, or uterus. The cases are mostly fatal.

Variola Minor. The following are the characteristics of the very mild form of the disease in England at the present time among the unvaccinated. The mortality is 0·4 per cent. The onset of the disease is sudden or insidious with headache, shivering, malaise, pyrexia, pain in the limbs and, exceptionally, back-ache—like influenza. There are no prodromal rashes or hæmorrhages, and no

prostration. The focal eruption does not appear constantly at the end of the third day, but sometimes as late as the seventh or eighth days. It appears first on the face, a few hours later on forearms and trunk, twelve hours later on the lower extremities. The pocks are smaller, more superficially situated, and their evolution is more rapid than in virulent small-pox. They fail to pustulate completely, but dry up into amber-like beads. The vesicles are unilocular. The distribution is the same as in ordinary small-pox. All constitutional symptoms disappear with the rash and there is no further pyrexia (13) (52).

The **Complications and Sequelæ** are chiefly as follows: abscesses and erysipelas, conjunctivitis, and sometimes destruction of the eye from suppurative keratitis; chronic otitis and caries of the bones of the ear; in the respiratory system, bronchitis, broncho-pneumonia, and pleurisy and the changes in the arynx above described. On the side of the nervous system the following may occur: hemiplegia, probably from arterial thrombosis or encephalo-myelitis similar to that following vaccination.

Diagnosis. This is best considered according to the stage of the disease: (1) In the pre-eruptive stage, the occurrence of shivering, with severe pain in the head and back and vomiting, characteristic of small-pox, might also suggest influenza, acute rheumatism, lumbago, or other acute diseases. (2) Early eruptive stage: The petechial eruptions on the lower parts of the abdomen and in the groins are very characteristic, but when the hæmorrhages are more generalised (*purpura variolosa*), purpura, septicæmia and other causes of petechiæ, *e.g.* scarlet fever and food-poisoning, must be differentiated. The erythematous eruptions may closely simulate scarlatina or measles. The scarlatiniform eruption of variola is not punctate and is unaccompanied by inflammation of the throat. The morbilliform eruption is not raised like that of measles and is rare on the face. Syphilis also sometimes presents an eruption like it. (3) The specific eruption in the papular stage, appearing first on the face and often grouped in twos and threes, may resemble papular erythema, *e.g.* a papular measles rash. (4) In the vesicular stage, small-pox must be differentiated from chicken-pox (considered later on, p. 35) and pemphigus. (5) In the pustular stage, it may resemble pustular eczema. (6) In the crusting stage it may resemble chronic eczema or exfoliative dermatitis. (7) Finally, it is necessary to consider the possibility of an individual being recently scarred with small-pox, and this may give the clue to the nature of an obscure acute affection in other members of the family. Careful account must also be taken of the recent history of the patient.

The **Prognosis** of variola major depends on vaccination. Nearly all persons attacked in the first few years after vaccination recover. In later years any protective action may be difficult to trace. The typical hæmorrhagic form is always fatal. About one-third of ordinary confluent cases die, and 5 to 10 per cent. of discrete cases. The profuseness of the suppuration is the surest measure of the fatality.

Treatment. The general lines of treatment are the same as for the infectious diseases already described. The patient must be isolated.

When small-pox is fatal death occurs most commonly in the stage of secondary fever from suppuration of the pocks. The method introduced by Dreyer of Cairo in 1910 is the best treatment for severe small-pox. The skin of the whole body is painted over with a 3 or 5 per cent. permanganate solution once daily. A 1·5 per cent. solution may be used if the skin is sensitive. In confluent cases it is best to place the patient in a permanganate bath at body temperature for a quarter of an hour twice daily. This treatment, if begun early, lessens the suppurative process, prevents the formation of bedsores and general sepsis, increases the comfort of the patient, and lessens the risk of infection of the attendants. Opium may be given to procure sleep. In the severer cases stimulants may have to be given freely.

If an unvaccinated person has incurred the risk of small-pox he should be vaccinated at once, as it is certain that the disease may be favourably modified by this procedure.

VACCINATION

The virus of vaccinia or cow-pox are ultra-microscopic elementary bodies known as Paschen bodies ; they are agglutinated by anti-vaccinal sera.

Prevention of Small-pox. *Inoculation and Vaccination.* The observation that small-pox, when conveyed by inoculation of the contents of the vesicle under the skin, produced a milder attack than that commonly conveyed by contagion, led to the use of inoculation as a means of protecting the individual from the more dangerous forms of the disease. Lady Mary Wortley Montagu introduced the custom into England in the early part of the eighteenth century, and her example was widely followed. But a serious disadvantage attached to this proceeding : the small-pox induced by inoculation, though mild, was contagious, and the spread of the disease was thus decidedly favoured. Inoculation consequently fell into disrepute, and finally yielded to vaccination—*i.e.* the inoculation of *cow-pox*, or *vaccinia*—first practised by Jenner in 1796. He was led to make the experiment from the facts, long observed in dairy farms, that cows were liable to a pustular disease of the udders and teats, which was often accidentally communicated to men and women milking them, and that these persons were subsequently insusceptible to small-pox, either by contagion or by the inoculation then in vogue. Conversely it was observed that those who had had small-pox did not catch the disease from the cows. Jenner inoculated patients with cow-pox, which produced its characteristic effects, and he subsequently found that certain of these patients were insusceptible to a small-pox virus, which set up typical variola in other unvaccinated persons.

The cow-pox may be conveyed from man to man by means of the lymph contained in the vesicles a great many times without any very obvious diminution of its power to reproduce the disease and to protect from variola. This arm-to-arm vaccination was in common use in the early days, and occasionally caused syphilis and other diseases to be transmitted, so that it has now been superseded by the use of lymph obtained direct from the calf previously inoculated with the virus. The introduction of this lymph was much facilitated by Copeman's demonstration that by thoroughly incorporating six parts by weight of a 50 per cent. solution in water of chemically pure glycerin with one part of the calf lymph or vesicle pulp, and afterwards storing the mixture for some weeks prior to use in sealed capillary tubes protected from light, any streptococci or staphylococci existing in the lymph, and even tubercle bacilli if introduced, are completely destroyed. The use of *glycerinated calf lymph* was recognised in the Vaccination Act of 1898.

The Method of Vaccination. The part selected for the operation is generally the outer side of the left arm, near the insertion of the deltoid muscle. The skin is first thoroughly washed and rendered aseptic, and put on the stretch by the use of the left hand. The vaccine may be introduced intradermally by needle and syringe ; but usually a drop of lymph is placed on the skin and one line or scratch $\frac{1}{4}$ in. long is made just through the epidermis in the long axis of the limb and through the lymph. The lymph may be rubbed gently into the scratch with the side of the knife or needle used. If a prompt successful vaccination is required, up to four inoculations may be made on different parts of the arm. After the lymph has dried the spots may be painted over with flexible collodion, but later on when a vesicle occurs a pad of boric lint should be applied.

The English law requires that all children should be vaccinated before the age of six months, unless the parent makes a statutory declaration of his conscientious belief that the proceeding will prejudice the child's health. But vaccination should only be carried out if the child is healthy, *e.g.*, not suffering from

diarrhœa or eczema ; unless absolutely necessary owing to presence of small-pox, vaccination should not be performed if the child has been exposed to infectious disease or if erysipelas is present in the house. It should be pointed out that there are at present two views as to how vaccination is to be used to prevent small-pox. One view insists on the importance of infant vaccination, with periodic re-vaccination as far as possible, and that individuals who have been in contact with a small-pox case shall also be vaccinated. The other looks on infant vaccination as unimportant, so long as vaccination of contacts is carried out. Vaccinal encephalitis, described later, is a very rare complication of vaccination, affecting chiefly children between five and fifteen who are vaccinated for the first time between these ages. The Minister of Health is of opinion that so long as variola minor alone is prevalent in this country it is not expedient to press for primary vaccination of such children. It has been recommended that infant vaccination should be carried out with lymph diluted 1 in 10, which incidentally gives much more satisfactory "takes" (8).

Vaccination in Man. When lymph from a vesicle of cow-pox is inoculated under the human skin, nothing occurs till the end of the second or the third day, when a papule appears at the seat of inoculation. This increases in size, and on the fourth or fifth day a vesicle forms, which enlarges and forms a circular bleb, flat or slightly depressed in the centre, and pale grey in colour. On the eighth or ninth day the contents begin to be purulent, and a pink zone of inflammation forms around it. The vesicle becomes more opaque ; the redness increases in extent, and is accompanied by induration. The neighbouring lymphatic glands become swollen and tender, and a slight degree of fever and malaise is present at this time. About the tenth or eleventh day the pustule begins to dry, and a brown scab forms during the next few days. The surrounding inflammation subsides, and about the end of the third week the crust falls off, leaving a depressed, pitted, and permanent scar.

Vaccination is, in the vast majority of cases, a perfectly harmless procedure, but occasional accidents are observed. Erysipelas may attack the wound of vaccination, as it may any other wound by accidental infection ; and gangrene has very rarely occurred. A rare complication is post-vaccinal encephalomyelitis, described later.

Cases of *aberrant vaccinia* are sometimes observed. Milkmen may become inoculated on the hands while milking, and in a case seen by the writer inoculation on the cornea led to blindness in one eye. Secondary vaccinia on the lips, tongue, tonsil, eyelids, etc., have been reported in individual cases, following ordinary vaccination on the arms.

Revaccination. The extent to which the first vaccination is efficient is generally estimated from the number and depth of the scars, and amongst fatal cases in epidemic times an inverse proportion has been shown between the number of the scars and the percentage of fatal cases, the mortality being least in those with four or more scars, greater in those with only one scar, and most of all in those stated to have been vaccinated, but without any visible scar at all. But in any case the protective influence of vaccination has only a limited duration, probably from twelve to fifteen years. It thus becomes desirable that every one should be again vaccinated in childhood or early puberty, and subsequently at any age, if small-pox should become epidemic. According to the extent to which the influence has faded, revaccination will have different results. It may fail entirely, or only produce a little local irritation ; or it may produce a typical vesicle.

CHICKEN-POX

(*Varicella*)

Chicken-pox is a specific infectious disease characterised by an eruption of vesicles. The nature of the virus is unknown. It commonly occurs in children,

but may attack both infants and adults. Contagion is conveyed by the air or by clothes, and possibly by the pus from vesicles or scabs, as it has been successfully inoculated. An attack confers immunity, as a second attack in the same person is quite uncommon. Although it has often been confounded with small-pox, it is certainly a different disease: vaccination does not protect from varicella, nor varicella from small-pox. The association of varicella and herpes zoster is close; are both due to the same virus? (*see Herpes Zoster*).

Symptoms. The period of *incubation* is eleven to nineteen days. The eruption consists at first of pink spots or papules, on which, in twelve or twenty-four hours, vesicles form. These are generally tense, hemispherical, and from $\frac{1}{8}$ to $\frac{1}{4}$ inch in diameter. At first the fluid is clear and colourless, but it soon becomes opalescent or milky, and then the vesicle shrivels, and a yellow or brown scab forms, which adheres for a few days, and then separates, leaving a pink stain. The perfectly formed vesicle is surrounded by an inflammatory zone, which subsides as the vesicle dries. They are more superficial and less loculated than in small-pox. Some of the pocks, but never a large number, result in depressed cicatrices.

The period of invasion is represented by febrile reaction, which is generally very slight; a diffuse or patchy erythema may come out before the proper rash, which, however, shows itself within twenty-four hours. It appears earliest, and is seen most commonly on the chest, but the face, trunk, and limbs are also affected. The spots are not very numerous, but fresh ones form for two or three days after the first appearance, and altogether they number, as a rule, from fifty to 200. A few vesicles form on the mucous membrane of the mouth, palate, and lips. Whatever fever preceded the vesicles continues for a few hours, or for two or three days; it is generally not above 102° , but may reach 104° . The lymphatic glands of the neck may be enlarged. Very occasionally encephalitis is a late symptom (*see later*).

In *varicella gangrenosa* some of the vesicles increase in size, become purulent, form reddish-brown or black scabs under which the skin sloughs, and ultimately leave circular ulcers with clean-cut edges. The child becomes very ill, and death may take place. In *V. bullosa* large bullæ are found in addition to the usual vesicles.

Cases have been recorded in which *hæmorrhage* has occurred into and around the pustules, as well as at other points in the skin; while there have been bleeding from the nose, mouth, vagina, and rectum, and petechiæ under the serous membranes. Most of these cases have ended fatally.

Treatment of Varicella. Children should be isolated, but confinement to bed is not often necessary. Light diet and attention to the bowels are often all that are required.

Differential Diagnosis of Small-pox and Chicken-pox. Varicella is sometimes difficult to distinguish from modified small-pox, and in epidemics of the latter it has been found desirable to make varicella "notifiable" (*see p. 13*), so that no case of small-pox may escape the attention of the sanitary authorities. Since the differential diagnosis of these two conditions is one of the most important issues in the diagnosis of fevers, it is treated at some length. *See also* Diagnosis of Small-pox (*p. 32*). In the first place the patient must be examined in a thoroughly good light, and as much of the skin as possible should be seen at one time by making the patient take off his clothes and use a blanket as a covering.

According to Wanklyn (2) the four most important groups of clinical phenomena are as follows:

(1) Prostration. This is usually a reliable sign of small-pox when considered in proportion to the density of the rash. A copious rash preceded by complete absence of prostration is strongly against small-pox.

(2) Distribution of the rash is the most important of all. Killick Millard (2) writes as follows: " (1) Ignore the head and neck. (2) Divide the rest of the

body into (a) trunk and (b) limbs. Then, if the lesions on a careful count be more numerous on the limbs, the case is almost certainly one of small-pox ; whereas if they be more numerous on the trunk it is almost certainly chicken-pox. It is true that there are a few cases in which the lesions may be almost equally divided, and in order that any error may be on the safe side—that is, in the direction of suspecting small-pox even though the case be one of chicken-pox, rather than *vice versâ*, it is well to weight the test by counting the buttocks and shoulders as being part of the limbs ; though in reality I believe that these regions should be counted with the trunk if the test is to give the greatest proportion of correct results."

(3) Localisation or depth in the skin. In varicella the papules are superficial, in small-pox deep. It is specially useful to regard those lesions which occur on the tenderer portions of the skin, such as over the axillæ, chest, or flanks ; relative depth in the skin is more readily appreciated in such situations, and by rolling a loose fold between the finger and thumb.

(4) Maturation. This means that the rash of small-pox tends to progress at a definite rate. In *varicella* vesiculation of papules occurs within a few hours, and is complete within twenty-four or at most forty-eight hours, the contents being turbid and not often really purulent. The pocks dry up in two or three days from the onset of the rash. In *small-pox* vesiculation of the papules is usually noticed on careful examination after forty-eight hours. It takes another four days before it is complete. Nearly all the pocks pustulate in severe small-pox, but the change is not complete until the sixth day of the rash. In *variola minor* fewer pocks become pustular. The whole rash may abort in the vesicular or semi-pustular stage. If a rash is papular and remains so for three or four days it cannot be small-pox. A hæmorrhagic case is often diagnosed by the supervention of the papular rash ; that is only to say again that the rash of small-pox develops and matures.

MUMPS

(*Specific Parotitis*)

Mumps is a specific contagious disease, of which the essential lesion is an inflammation of the parotid gland.

It occurs mostly in children and young adults ; young infants, as well as elderly people, are more rarely affected. Males are more susceptible than females. No micro-organism has been identified ; but it appears that the virus is filterable, like that of poliomyelitis ; and serum from the diseased parotid, injected into monkey's parotids, has produced symptoms comparable with those of mumps.

Symptoms. The period of *incubation* is fourteen to twenty-eight days. The commencement may be shown by slight malaise for a day or two, but the first symptom is often a feeling of pain and stiffness in the jaw and cheek of one side. Swelling then takes place just beneath the lobule of the ear, so that this is pushed out, and the depression between the jaw and the mastoid process is filled up. The swelling then spreads lower, beneath the ramus of the jaw, and may involve the sublingual and submaxillary glands. After a day or two the glands of the other side become involved, and thus there is a collar of swelling round the whole jaw from side to side. The swelling is pale, shiny, doughy in consistence, and tender when touched ; but suppuration rarely takes place. Internally the tonsils and fauces are somewhat swollen. As a result the teeth can be separated with great difficulty, and not for more than half an inch or so ; and mastication and deglutition are very painful, the pain on movement of the jaw being darting, and lasting for some time. The secretion of saliva may be normal, or increased, or diminished. There is a moderate degree of fever, the temperature rising often to 102°. There is a relative and absolute increase of the lymphocytes in the blood, and this condition lasts for fourteen days. The swelling lasts from seven to ten

days, and slowly subsides ; and the patient is usually quite well within three weeks. Occasionally the skin over the gland desquamates. Cases of mumps have been described, in which the submaxillary glands have been alone affected.

Complications. As a result of mumps it happens occasionally that *orchitis*, or inflammation of the testicles, occurs just as the parotitis is subsiding, *i.e.* about the seventh or eighth day ; but it may be earlier or later than this, and may, indeed, precede the parotitis. It occurs in from 20 to 30 per cent. of male cases, and is more common in adults than boys. The process begins in the epididymis ; the testicle swells, and there may be effusion into the tunica vaginalis and œdema of the scrotum ; it is accompanied by pain and tenderness, a rise in temperature, which may reach 104°, and in rare cases by acute delirium. The inflammation subsides in a few days, but it may be followed by a permanent atrophy. More rarely there is double orchitis. In females the mammæ may inflame (*mastitis*) or the external genitals swell, and rarely the ovaries are tender. Mastitis has also been seen in boys. *Pancreatitis* has also been recorded, occurring generally at the end of the first week, and lasting from two to seven days ; but it has been known to precede the parotitis. It is shown by pain in the epigastrium and left hypochondrium, tenderness and swelling in the same region, pyrexia, nausea, vomiting, and occasionally by diarrhœa or the passage of fat in the stools. Diabetes has also been described. Meningitis, optic neuritis, otitis, peripheral neuritis, bulbar paralysis, endocarditis and nephritis are rare sequelæ.

The **Anatomical Change** in mumps is an inflammatory infiltration, serous and cellular, of the interalveolar fibrous tissue of the salivary glands.

The **Diagnosis** presents no difficulties, and the **Prognosis** is favourable.

Treatment. The patient should remain in one room ; and confinement to bed is believed to lessen the liability to complications, especially in males, in relation to orchitis. Locally fomentations generally give relief.

INFLUENZA

This term, often wrongly applied to any severe nasal catarrh, is the name given to an acute febrile disease which in past times has frequently swept as an epidemic over Europe, but which was practically unknown among us after the violent outbreak of 1847-48 until the winter of 1889-90, when it again appeared. On this occasion it was first observed in Bokhara in the preceding May ; it appeared at St. Petersburg in October, and soon invaded Austria, Germany, France, England, and other European countries, as well as the United States of America. A few months later it was conveyed to India, Australia, New Zealand, the African coast, and South America. The disease has again frequently broken out in the British Isles, and of late years has rarely been entirely absent. The last great epidemic, which appeared first of all in Spain, broke out in England in the form of three waves : the first and slightest in point of mortality in June and July, the second and most severe in November, 1918, and the third in February and March, 1919. It is a characteristic of influenza that, while children and elderly people usually escape death, the disease is particularly fatal between twenty and forty years of age.

Lesser epidemics, milder in form, characteristically precede and follow the major epidemic, the next visitation of which is prophesied between 1945 and 1955. Further, it would seem that before and after a major influenzal epidemic there are seen in epidemic form various diseases of the nervous system, of which the most consistent seem to be poliomyelitis, cerebro-spinal meningitis, and encephalomyelitis (lethargic or spasmodic) (19).

Ætiology. The true epidemic invasions of influenza have always been characterised by the extraordinary rapidity with which the population has been attacked, especially in crowded towns. Hundreds have been struck down at

the same time. This feature was especially marked in 1889-90. Infection takes place by inhalation of droplets of sputum or saliva projected into the air during coughing and speaking.

In 1892 Pfeiffer discovered a minute bacillus, which is commonly present in the sputum of influenza patients and less commonly in the blood. It is called the *Hæmophilus influenzae*, and until recently has generally been regarded as the cause of influenza. The bacillus has been cultivated post mortem in 98 per cent. of cases of pneumonic influenza. But it is also present in various parts of the respiratory tract in a smaller proportion of people who have died of quite other diseases (18).

However, evidence has been forthcoming (20) that the cause of the disease is a virus or minute filter-passing organism. It is obtained from the nasal secretions of patients early in the disease, when the *H. influenzae* is often absent, and influenza has been produced by cultivation of this organism, which has been named the *Bacterium pneumosintes*. Bacteria-free washings from the nasal mucous membrane of influenza patients, but not from a subject with a common cold, have been found to infect ferrets, and the disease can be passed on from ferret to ferret, while serum from influenza convalescents neutralises the virus of the ferret disease. The *H. influenzae* probably plays an important but secondary rôle in the disease by producing the various respiratory complications; this has been proved to be the case with swine influenza, the virus by itself producing a very mild form of attack, while the fully developed disease results from a symbiosis of the virus and the influenza bacillus. An attack of influenza protects the subject for some months at least, but the acquired immunity is not indefinite. In the last epidemic about 20 per cent. of patients had had previous attacks.

Morbid Anatomy. Tracheitis, bronchitis and bronchiolitis are always present. There may be extreme congestion of the lungs, hæmorrhagic œdema or diffuse hæmorrhage without consolidation, or on the other hand solid hæmorrhagic areas involving a whole lobe, or occurring in patches like infarcts. There may be broncho-pneumonia or multiple abscesses, usually small and aggregated, or actual gangrene. There may be multiple small areas of collapse or massive collapse. Peribronchitis and interstitial emphysema may occur, and also pleurisy with or without effusion. The bronchial glands are inflamed. In most cases the sphenoidal sinuses and other accessory air sinuses are infected. The primary focus of the infection in the body is probably situated in the nasopharynx. The kidneys contain excess of blood, but otherwise look normal (see Acute Nephritis).

Symptoms. The incubation period is from just under forty-eight hours to five days. There is the greatest possible variety in the manifestations of influenza. In a large number of cases the symptoms are those of an acute febrile illness, without special determination to any one organ or system of the body. This may be described as the *simple* type, or *simple febrile* type.

The disease begins suddenly with severe frontal headache, pains at the back of the eyes and muscular aching and pains in the muscles of the loins, thighs, calves, and other parts of the body. Rigors are often absent, but the temperature rises within a few hours to 102°, 103°, or 104°. The other accompaniments of fever are present, such as quick pulse, thirst, and scanty, high-coloured urine. The systolic blood pressure falls by 10 or 20 mm. (54). The tongue is flabby, tremulous, indented, and covered with a thick white fur. The fauces and tonsils are red, and the breath is offensive; epistaxis is fairly common. The skin is generally dry, but there are sometimes profuse perspirations. The spleen is sometimes slightly enlarged. The patient is exceedingly ill, restless, sleepless, prostrate and depressed. No other symptoms may appear, and the temperature falls in twenty-four, thirty-six, or forty-eight hours as rapidly as it rose; but the general pains in the limbs continue for some time after the temperature has fallen,

and the sense of prostration, which is present from the first, persists for some days after the fever. However, it must be admitted that there is much variety in the course and duration of cases in this group ; and that while in some the fever is high, of short duration, and falls rapidly, in others the course is longer, and the fall of temperature more gradual, so that a confusion with other febrile illnesses, such as typhoid fever, is rendered possible. In either case there may be a relapse.

In the *pneumonic* type of the disease, which occurred in about 20 per cent. of cases ill enough to be admitted to hospital at Aldershot during the 1918-19 epidemic, the commencement presents the same features, namely, fever, headache, pains in the limbs, and prostration ; but it is soon seen that the respiratory tract is largely involved. There are rapid breathing, pain in the chest and troublesome cough. The signs in the chest are extremely variable : there may be no signs except a few scattered rhonchi in front and some crepitations behind ; again, the signs may resemble those of a lobar pneumonia ; again, râles may be heard everywhere with no signs at all of consolidation ; again, consolidation may appear in one part of the lung to be replaced on the next day by vesicular murmur, but to appear in another part of the lung ; again, signs of fluid may be present. The prognosis cannot be gauged at all by the extent of consolidation of the lung. The sputum may be either purulent and abundant or blood-stained, tenacious, frothy, and rather scanty. In the most serious cases there is a uniform heliotrope cyanosis over the face, associated with marked deficiency of oxygen in the arterial blood. Nephritis occurs in the majority of pneumonic patients. There is no œdema usually, but the urine contains albumin and casts. Nasal catarrh with suffusion of the conjunctivæ is occasionally a condition of influenza, but both the simple and respiratory forms commonly occur without them.

The *abdominal* type is less frequent, but varies with different epidemics. The patient has abdominal pain, diarrhœa, vomiting, and occasionally jaundice. The temperature is often less high than in the preceding forms.

Both the respiratory and the gastro-intestinal symptoms may appear to be rather complications and sequelæ than parts of the original disease ; that is, the fever and pains may be present for a few days before either of these systems is manifestly involved. Other systems are also involved more often secondarily or rather late in the history. Sometimes the pulse is irregular or intermittent, due to auriculo-ventricular or sino-auricular heart block ; there may be syncopal attacks. Tachycardia also occurs, and the heart may show evidences of dilatation. Hæmorrhages from the different mucous surfaces are sometimes observed.

The nervous system is frequently involved. Drowsiness occurs in early stages, with delirium in severe cases. Later there may be sleeplessness, a persistent neuralgia, or muscular pains. In a large proportion of cases, and without any special localisation of symptoms in the nervous system, there is prolonged weakness of the limbs, inability for physical and mental exertion, and great mental depression lasting for months after the beginning of the attack. The skin is occasionally the subject of eruptions in the height of the attack, or a little later. These are mostly in the form of rose-coloured spots, or erythematous rashes like those of measles, scarlatina, or urticaria ; alopecia may occur. In addition there is scarcely any local inflammation that may not in some case or other appear as a sequel of influenza ; for instance, otitis, which is rather common, orchitis, peripheral neuritis, myositis, phlebitis, parotitis, pericarditis, meningitis, encephalitis, myelitis, conjunctivitis, keratitis, arthritis, and lymphadenitis. Amongst the sequelæ are loss of taste and smell and almost any type of mental disorder.

Early in the disease the blood shows a polymorphonuclear leucocytosis. This is followed by a leucopenia with a deficiency of polymorphonuclear cells and a relative lymphocytosis (21). If pneumonia supervenes there is a leucocytosis

with a great increase in polymorphonuclear cells. The hæmorrhagic nature of the pneumonia may be associated with the diminution of blood-platelets (*see* p. 446), which has been observed.

Diagnosis. The great variety that influenza presents will lead to its being diagnosed in the early days of an illness, when further acquaintance with the case may show it to be some other febrile complaint, such as pneumonia, and especially enteric fever (*see* p. 78). The very sudden onset, the local pains, low systolic pressure, and the short fever are the chief distinguishing points of influenza; but there are slight cases which can only be diagnosed by way of exclusion, by the amount of depression succeeding it, or by its complications and sequelæ.

Prognosis. Death only occurs in a small proportion of cases attacked. Cyanosis in a pneumonic case is always a bad sign, and if the temperature suddenly falls in such a case, it is almost hopeless.

Prevention. There is statistical evidence that prophylactic inoculation with a stock vaccine containing 400 million *H. influenza*, 80 million streptococci and 200 million pneumococci prevents the onset of influenza or rather prevents the onset of the complications, which are the main part of the disease. It is important for all persons in attendance on influenza patients to wear masks consisting of several layers of butter muslin. In the last epidemic such masks were worn with effect by people in crowded places. The evidence in favour of taking quinine as a prophylactic is not good. The instillation into the nose of Glegg's paraffin and vaseline mixture, so effective against coryza (*see* p. 196), is well worth a trial during an influenza epidemic.

Treatment. The patient should save his strength by at once taking to his bed and the general treatment of pyrexia instituted. In the early stages the severe pains call for treatment, and may be met by sodium salicylate (10 to 15 grains every four or six hours), by aspirin (7 to 10 grains), or by phenacetin (5 to 6 grains). The great tendency to prostration after the illness makes it necessary to give these drugs with caution. Bronchitis or pneumonia may require treatment.

ACUTE POLIOMYELITIS

(*Acute Anterior Poliomyelitis, Acute Polioencephalitis, Heine-Medin's Disease*)

For years it has been known that children were liable to suffer from paralysis and atrophy of one or more limbs, or part of a limb; and that this paralysis was due to an acute inflammation of the anterior grey cornua of the spinal cord. Such cases were called *infantile paralysis*, and later *acute anterior poliomyelitis* (πολιός, grey). These cases occur sporadically, but two or more members of one family may be affected, and there are sometimes epidemics. Although the disease attacks the spinal cord most frequently, it may also attack any other part of the central nervous system. The term *polioencephalitis* has been used for certain of these cases; but it is best avoided, so as to prevent confusion with acute encephalitis, which is closely related, but is a different disease.

Ætiology. Whether sporadic or epidemic, the disease attacks infants or children with much greater frequency than adolescents or adults; for instance, in a large epidemic two-thirds of the cases were under six years of age, and five-sixths under ten years. It is most frequent in the summer and autumn months. The micro-organisms causing the disease are minute globoid bodies arranged in pairs, measuring 0.15μ to 0.3μ in diameter; these are so small that they readily pass through a porcelain filter; they can be cultivated anaerobically on a special medium, and cultures reproduce the disease by inoculation into monkeys, from which animals the organism can be again recovered in pure culture (Flexner and Noguchi, 1913). Washings from the nose, mouth, pharynx, upper air passages, and small intestines of patients when filtered produced the disease in monkeys,

and there is evidence that healthy people may act as *carriers*. The disease may also be spread by patients who have the *abortive* form of the disease. There is considerable doubt as to whether the virus is conveyed by flies, dust, or external objects. Milk was a vehicle in one small epidemic (33). It is believed to pass to the central nervous system along the axons of the peripheral nerves, and the axis cylinders of the olfactory nerves, which lie exposed in the nasal mucous membrane, may be the sole means of approach. The virus passes through the brain by axonal channels and has a special affinity for the grey matter of the cervical and lumbar enlargement. Paralysis may occur in domestic animals, particularly during epidemics; but they are probably not due to the same disease.

Morbid Anatomy. The essential lesion is in the nerve cell. The nerve cells, especially those of the anterior cornua, present various degrees of degeneration up to complete disappearance; and they may be seen infiltrated with polymorphonuclear and mononuclear cells (*neuronophagia*). The lesion of the anterior cornua is followed by secondary degeneration of the nerve fibres of the motor roots, and atrophy of the muscles supplied by them. Some secondary changes take place in the white matter, and the meninges. The pia mater is oedematous and infiltrated with mononuclear cells; there is oedema of the affected part of the cord, proliferation of cells in the sheaths of the blood vessels both in grey and white matter and in the meninges, and cell infiltration of the substance of the grey matter. The same acute processes may occur in patches in the medulla, pons cerebrum, cerebellum, and meninges.

In some fatal cases, in addition to the lesions of the nervous structures, the lymphoid tissues of the small intestine, the thymus and the spleen have been enlarged, and there has been some degeneration of the gland cells of the liver.

In cases dying after years of permanent atrophy of one or more limbs, the cord presents changes obvious to the naked eye. The motor nerve roots, coming from the part presumably affected, are diminished in size and number. On a transverse section the cord is smaller on the affected side, and the anterior cornu is shrunk. Under the microscope there is an almost entire absence of motor nerve cells and axis cylinders; the few nerve cells that remain are smaller than normal, shrunk, fusiform, and wanting in processes, and lie in a dense felt-like overgrowth of neuroglia. The motor nerve roots, both in and beyond the cord, show the destruction of axis cylinders, and are obviously degenerated.

The muscles in physiological connection with the damaged parts undergo fibrous or fatty degeneration, which may be partial or complete. They are pale pink, watery in appearance, and present under the microscope changes due to lesions of motor nerves.

Symptoms. For the sake of convenience, a number of clinical forms of the disease have been described depending on the part of the central nervous system attacked. It must be remembered that individual cases are often a mixture of two or more forms. Certain *general symptoms* common to all forms may first be described. The period of *incubation* is from four to twelve days. The onset is rapid: there are feverishness with headache, and drowsiness, and severe pains in one or more limbs, suggesting acute rheumatism. The pain is increased on movement. Convulsions, vomiting and diarrhoea sometimes occur. While drowsy the patient may pass urine and faeces involuntarily. There may be a diffuse erythema, or a vesicular rash, and occasionally herpes zoster. Tingling or formication may accompany the pain in the early stages, but there is never any considerable loss of sensation, and the above symptoms pass away in a few days. Catarrhal symptoms—nasal discharge, cough, sore throat—are uncommon.

The cerebro-spinal fluid in about 80 per cent. of the cases shows an increased cell count in the first week of the disease; in the earliest stages this may consist largely of polymorphs, but after the first two days lymphocytes predominate, and at the end of the first week polymorphs are seldom found. By the end of

the second week the cell count is usually normal. The protein almost always shows a slight increase; this occurs in the second week of the illness, and often persists after the cell count has returned to normal. The sugar and chlorides are not diminished.

1. *Spinal Form.* This accounts for about three-quarters of the cases. It usually shows itself as a paralysis of the limb muscles; but the muscles of the trunk, abdomen, and neck are also sometimes involved.

In the course of twenty-four or forty-eight hours it is found that there is weakness or definite paralysis of certain muscles, or a child may go to bed well and be found to be paralysed in the morning. It frequently happens that three or four limbs are paralysed at first, and recovery quickly takes place in two or three, leaving the others permanently affected; in other cases, certain limbs are affected from the first and remain so. The paralysis, however, need not involve the whole of a limb, but, it may be, only a part of it, or even one muscle group. If paralysis affects both legs, or the arm and leg on one side, it is not distributed uniformly, as in some other forms of paralysis. The affected muscles rapidly undergo atrophy, lose bulk, and become flaccid; when tested electrically some days after the onset they show the reaction of degeneration or in severe cases do not respond at all to either current. All the deep reflexes are lost in the most affected parts, and generally the superficial reflexes as well.

Although the disease in most cases attacks principally the grey matter of the spinal cord, a complete transverse lesion is occasionally seen; in the cervical region such a case shows loss of power and wasting of the muscles of the hands and arms and spastic paralysis of the legs. Mention must also be made of certain "jump" cases. The disease may, for instance, involve the legs and remain stationary for some days, when a more widespread paralysis affecting the muscles of the trunk or upper limbs suddenly takes place, or this extension may take place gradually. It may pass downwards along the cord as well as upwards. Some of these cases closely resemble Landry's paralysis. In addition, *relapses* may take place after some weeks' interval.

At the end of the febrile period the muscles which remain paralysed after the first partial recovery will themselves improve only very slowly after weeks and months. The amount of impairment in the use of the limbs will depend on the number of muscles atrophied; but after a time, in many cases, lost movements are restored by fresh combinations among the muscles which have been spared. Atrophy is, in almost all cases, a prominent feature, hollowing out the rounded part of the forearm, or reducing the upper arm or the leg to a mere stick. Sometimes, however, the loss of muscle may be entirely concealed by the presence of fat; the flabby condition of the muscle even then can be generally recognised. Associated with the atrophic condition of the muscles is generally a change in the vascularity of the limb; it is cold, shrunk, and blue or livid from retarded circulation. The nutrition of the bones and other parts is also involved, so that a limb paralysed in infancy or early childhood does not grow with the same rapidity as its fellow, and may be shorter by $\frac{1}{2}$ inch, 1 inch, or more. Lastly, deformities may occur besides those directly due to loss of muscular substance, owing to faulty treatment. Some are the simple result of failing muscular support; thus, from atrophy of the deltoid, the humerus falls from the glenoid cavity. Others consist of permanent changes in the position of the limbs, such as talipes equinus, which so often results from paralysis of the anterior tibial muscles.

2. *Bulbar, Pontine, and Mid-brain Forms.* Any of the cranial nerve nuclei may be attacked as well as the tracts passing through this part of the brain. The seventh nerve is the one most commonly affected. Some cases hitherto diagnosed as Bell's palsy are due to poliomyelitis.

3. *Cerebral Form.* Hemiplegia is the commonest manifestation of this form of the disease; but it is not a common cause of hemiplegia in children, accounting for at most 10 per cent. of the cases (*see also encephalitis*). Athetosis is rare.

4. *Cerebellar Form* is indicated by the occurrence of cerebellar ataxy, the characteristics of which are described later.

5. *Meningitic Form*. Symptoms of meningitis are not at all uncommon in acute poliomyelitis. After severe headache the patient may become comatose with rigidity of the muscles at the back of the neck, with convulsions, and with typical changes in the cerebro-spinal fluid.

6. *The Abortive Form* is only recognised where there are epidemics of acute poliomyelitis. There are fever, headache, pains in the limbs, and general weakness, but no paralysis.

Diagnosis. The symptoms of fever, headache, vomiting, convulsions and pain may be caused by many acute illnesses, such as meningitis or pneumonia. The muscular power, the loss of which is the distinctive feature, should be critically examined from the first, in view of the fact that young children will not volunteer the information. After some days the diagnosis is confirmed by the rapid atrophy, by the loss of reaction to the faradic current, and the changed reaction to galvanism. The pain which is sometimes present may suggest *rheumatism*, but it is situated rather in bone and muscle than in the joints; in infants *scurvy* must be thought of. The disease may also be confounded with *Landry's paralysis*, with *multiple neuritis*, due to some other organism, to alcohol or other poison, or with acute myelitis, due to some other infection. Pain and tenderness are not usual in Landry's paralysis, but some cases described as Landry's paralysis have certainly been actually poliomyelitis. In the early stage, and in abortive cases, the diagnosis may often be established by examination of the cerebro-spinal fluid. The normal chloride content in poliomyelitis is a useful point in the differential diagnosis from tuberculous meningitis. A method of *serum diagnosis* is also available. This depends on the fact that a 5 per cent. emulsion of spinal cord containing the virus will cause the disease in monkeys if injected intracerebrally; but if mixed with an equal volume of serum from a patient who has recovered, it will be inert. By such means it is possible to find out definitely whether certain suspected cases had really had the disease, which would be valuable from the public health point of view.

Prognosis. In recent epidemics of this disease the mortality has varied from 10 to 20 per cent., a much higher mortality than was recognised in sporadic cases, in which life was not generally regarded as endangered. On the other hand, complete recoveries appear to be more frequent in epidemics. Death is due generally to respiratory paralysis or to broncho-pneumonia if the respiratory muscles are interfered with; it rarely occurs if the fourteenth day is safely reached. Not more than about 15 per cent. of cases show complete recovery. In the remainder most of the muscles originally paralysed eventually recover, but one or two groups remain permanently damaged. Most improvement takes place during the first six months, and it continues slowly for two years. After this time very little further improvement is likely to occur. Second attacks are extremely rare.

Prevention. Patients and contacts should have their nasal and buccal cavities frequently washed out with a solution of potassium permanganate of 1 to 2,000, to destroy the virus. The period of quarantine for contacts is fourteen days. The patient should be isolated for at least three weeks, and as long as there is any nasal discharge he should still be considered infectious. He may, like a case of typhoid, be treated in a general hospital ward.

Treatment. The general treatment for pyrexia is instituted. Aspirin or sodium salicylate may be given to relieve pain, or even morphia in extreme cases, in doses appropriate to the age. Hexamine may be given in doses up to 50 grains, as being an antiseptic which is secreted into the cerebro-spinal fluid, provided that the urine is kept alkaline; but estimates as to its value vary. More active measures have been advised, *e.g.* lumbar puncture, which relieves pressure, and with this the intraspinal injection of adrenalin chloride solution

(1 to 1,000) in doses of 1 or 2 c.c. every six hours, or the intraspinal injection of an immune serum, that is, serum obtained from the blood of persons who have suffered from the disease months or years previously, in doses of from 10 to 30 c.c. daily (Netter). The serum of normal adults has also been found to render monkeys free from the disease when injected with the virus. The cases suitable for this treatment are (1) those in which the diagnosis can be made in the pre-paralytic stage; (2) those with symptoms of meningitis; (3) those in which the paralysis is extending. The treatment is useless for muscles which already show paralysis. Unfortunately, this treatment has recently been found to be useless when tested on a large series of controlled cases in New York, and in any case it has been argued on theoretical grounds that the serum should be administered intravenously rather than intrathecally (31).

Where there is respiratory paralysis life may be saved by means of the Drinker's respirator—a metal box in which the patient lies with the head projecting; the pressure inside the box can be varied so that the respiratory movements are performed. The Bragg and Paul apparatus might also be used. The chest is surrounded with an air-tight rubber bag furnished with an inextensible outer covering. The pressure in the bag is alternately raised and lowered by a motor pump. In these apparatuses treatment over weeks may be required. For shorter periods Eve's rocking method may be employed. The patient is fastened prone on to a stretcher, which is pivoted on a support like a see-saw. Tilting up and down causes the diaphragm alternately to descend into the abdomen and ascend into the chest.

The *immediate* treatment of the affected muscles consists in *rest*, in the so-called *neutral* position, so as to keep the muscles intermediate in length between contraction and relaxation. This position may be maintained by quite simple apparatus such as sand-bags or wooden splints. The correct position of the upper limb is with the thumb adducted, the fingers slightly flexed, the wrist straight and half-way between supination and flexion, the elbow slightly flexed and the shoulder partially abducted from the side. The lower limb should be placed with the foot at right angles to the leg and the knee slightly bent and the hip straight. When one leg is affected the other one should also be kept in splints to prevent asymmetry of the pelvis. In three or four weeks' time it will become obvious what special muscle groups are paralysed, and then the position of the limbs and body should be altered, so as to allow complete relaxation of the paralysed muscles, with a consequent overstretching of the healthy antagonists. In most cases this will mean that the shoulder must be abducted at a right angle and the wrist dorsiflexed. Light celluloid splints may be used, the splint being moulded on an accurate cast of the limb. If both legs and trunk muscles are paralysed, some degree of lordosis should be brought about by supporting the back in the lumbar region, as in this position the patient could eventually walk with the aid of retentive apparatus.

Re-education of paralysed muscles should begin as soon as the temperature has subsided and the pain has gone. This consists in getting the patient to use the muscles at stated intervals each day; he should attempt to move them himself, and even if no movement results the attempt should still be persisted in; the effect of gravity should be diminished or abolished, and the amount of work the muscle is called upon to do should be minimal to begin with. For instance, with a weakened quadriceps the knee is at first flexed to a small extent with the patient lying on his back, and he is told to straighten it. The amount of flexion is gradually increased. It is valuable sometimes to carry out these movements in a bath, as the water gives some support. Between the exercises the splints must be kept on, and during the exercises the paralysed muscle should *never* be allowed even for a moment to become overstretched, at any rate for the first few months. Galvanism should be used for completely paralysed muscles and massage after the first few weeks helps the circulation. The re-education of

the trunk and abdominal muscles can be best carried out by the patient walking about in the erect position. This can be done when the patient's paralysed legs have been splinted, if he uses a walking machine.

It must be recognised that if nerve cells are completely destroyed the muscular fibres dependent upon them will be irretrievably atrophied, so that later, surgical measures may be required.

PSITTACOSIS

This is a condition due to a filterable virus (27), which occurs among parrots (*ψιττακός*, a parrot), and in which enteritis, sometimes hæmorrhagic, is a prominent symptom. The disease is communicable to other small animals and birds, and also to man, probably by the feathers soiled with fæcal matter. In man the disease somewhat resembles typhoid fever. The incubation period is from seven to twenty-five days; and then occur suddenly fever with rather slow pulse, intense headache, generally occipital, anorexia, restlessness, delirium, abdominal distension, vomiting, diarrhœa and albuminuria. Broncho-pneumonia, with frequent cough, is observed in many cases, and the mortality is about 30 per cent. An epidemic occurred in Paris at a time when it became the fashion for ladies to carry about parrots as pets, and this disease again appeared in 1929 in this and other countries.

FOOT-AND-MOUTH DISEASE

(*Aphtha epizootica*)

This disease of cattle and sheep is occasionally transmitted to man. The typical feature of the disease in cattle is the formation of vesicles and bullæ on the mucous membrane of the mouth, lips, and tongue. The affected parts become swollen, and the saliva dribbles away. The vesicles break, leaving a grey layer covering the base. Vesicles also appear on the feet round the borders of the hoofs, and they become pustular and produce crusts. In cows vesicles form also on the udders and teats. There is a moderate degree of pyrexia. The disease lasts about a fortnight, and generally ends in recovery, except in calves, of which from 50 to 75 per cent. die, some from enteritis.

The disease appears to be conveyed to man by direct inoculation, and by drinking milk from an infected cow; but it may also be carried from man to man in boots or clothing.

The virus will pass the finest filter. The incubation is from three to five days. Slight pyrexia and loss of appetite first occur; then vesicles are observed in the mouth, on the lips, tongue, fauces, and hard palate. They reach the size of peas, become opaque, break, and form shallow ulcers, with a dark red base. The lips become swollen, and saliva and mucous are more abundant than normal. Mastication, swallowing, and talking are somewhat painful. There may be some diarrhœa and abdominal pain.

Sometimes vesicles form on the fingers, especially about the nails; they become pustular, and run together; and similar vesicles occur on the toes, on the soles of the feet, and on the nipples of women. The duration is from ten days to a fortnight, and the disease is rarely fatal.

Treatment. Washes of borax, of potassium chlorate, or of potassium permanganate should be used to the mouth, and painful ulcers should be touched with solid silver nitrate. Zinc or lead ointments or lotions to relieve itching should be applied to the eruptions on the fingers and toes.

GLANDULAR FEVER

This complaint, described by Pfeiffer, Park West, Dawson Williams, and others, consists of an inflammatory swelling of the deep cervical and other

lymphatic glands associated with fever. It may occur in epidemics, is mildly infectious, and affects chiefly children and young adults. It has an incubation period of from five to seven days. The patient is taken suddenly with stiffness in the neck, difficulty of swallowing, and febrile reaction, with anorexia and perhaps vomiting. The fauces are often reddened, but otherwise little affected. On the second or third day of pain the cervical glands, and generally those under the sternomastoid muscle and along its anterior border, are found to be enlarged and tender. In another day or two those of the other side are swollen, and the posterior cervical, axillary, and inguinal glands may be also involved. The glands on the left side are usually larger than those on the right. The enlargement may be delayed for two weeks or more or may be so slight as to escape notice (10). There is generally abdominal pain and tenderness; and the liver, spleen, and mesenteric glands may be enlarged. The glands begin to get smaller after from two to five days, and do not suppurate. The temperature may reach 104° on the third day, and it will continue high as long as the glands remain enlarged. Constipation is often troublesome. The disease subsides usually without complications; but hæmorrhagic nephritis occurs in 6 per cent. of cases, and convalescence may be retarded by anæmia. Various rashes have been described--macular, urticarial, and papular, as in paratyphoid fever, appearing after the fourteenth day of the illness. The bacteriology of the disease is at present negative. The characteristic blood change is an increase in the mononuclear cells, hence the name infectious mononucleosis; these are now regarded as always being lymphocytes though they may resemble hyalines; but they can be differentiated by *intra vitam* staining and the peroxidase reaction.

Diagnosis. The glands enlarge rapidly and there is no anæmia. In spite of the high temperature the constitutional disturbance is usually slight. This latter feature helps to distinguish the disease from acute leukæmia. Cases are often diagnosed as tonsillitis, mumps, acute tuberculous adenitis, or acute Hodgkin's disease (26). Paratyphoid fever may also be imitated.

The **treatment** consists in rest, a simple diet, the relief of the constipation by small doses of mercury or salines, and the use of preparations of iron during convalescence.

The following disease is due to Rickettsia :

TRENCH FEVER

During the great European war there was observed, at first almost exclusively in men returning from the trenches, but later behind the front, a form of febrile disease which presented new features, and was essentially different from anything formerly recorded.

Ætiology. The virus of trench fever is conveyed by lice. It has been transmitted by allowing lice that have fed on patients to feed on healthy men, and also by rubbing the excreta of infected lice into abrasions of the skin. There is good evidence that the virus of trench fever is a Rickettsia body. Although these bodies are difficult to find in patients, they appear in the body of the louse just when it reaches its most infective stage, *i.e.*, five to eight days after feeding on an infected patient.

Symptoms. The incubation period is from five to thirty days. The onset is somewhat sudden, and the patient suffers from headache, giddiness, sometimes nystagmus, shivering, and pains in the back and legs. Occasionally he vomits. There are three characteristic types of temperature chart: (1) The single short bout of fever, making the case resemble one of influenza. This is called the *short* form of the disease. (2) The *relapsing* type. The patient has an attack like that just described. After an interval of three or four days he is attacked by the same symptoms, and the temperature again rises, though not quite so high as in the original fever (*see* Fig. 4). (3) The type with the *prolonged*

initial fever, making the case resemble one of typhoid fever ; but the symptoms are the same as in the other types.

The disease may last for six or seven weeks, and it is not fatal. Tachycardia

FIG. 4.—Chart of Temperature in Trench Fever.

frequently develops, the disease being a common cause of effort syndrome in soldiers. For further details the last edition of this book should be consulted.

Bacterial Diseases—I. Micrococcal

STREPTOCOCCAL INFECTIONS

A complete description of streptococcal infections would probably mean a description of the greater part of medicine as dealt with in this book, which is quite outside this article, and a brief summary must suffice. Streptococci may gain an entrance into the body through the skin or mucous membranes primarily by themselves, or secondarily in the wake of some other primary invader, *e.g.* the ultra-microscopic virus of influenza. After entering the body they may become localised in one particular area, producing (1) characteristic acute infections—in the skin erysipelas ; in the throat tonsillitis which, when milk borne, may be epidemic, or in certain circumstances becomes scarlet fever ; in the uterus puerperal fever ; in the lungs broncho-pneumonia ; in the urinary tract pyelitis ; in the joints arthritis, and so forth—or (2) a subacute or low-grade infection—on the heart valves subacute bacterial endocarditis—possibly also acute rheumatism, in the periarticular tissues rheumatoid arthritis, in the tonsils chronic septic tonsillitis, etc.

By special bacteriological technique sixteen types of streptococci have been isolated, and evidence has been forthcoming that some of these strains may be converted into each other by modifying the culture media, etc. For clinical purposes streptococci are commonly divided into two groups : (1) the *S. hæmolyticus*, which on culture hæmolyses the blood cells, and which is usually isolated from acute infections and from some chronic infections too, and (2) the *S. viridans*, which forms a greenish pigment on blood media (probably due to partial hæmolysis), which appears exclusively in low-grade infections. But as in other infections, it is not only the virulence of the streptococcal invader, but the constitution of the host, that determines the exact nature of the infection. Hæmolytic streptococci have three properties apart from causing hæmolysis ; they produce an erythrogenic toxin, which is dealt with in scarlet fever ; they are pyogenic, and no anti-body has been prepared against this, and they invade

the tissues (15). In this connection Lancefield has found three different bodies among the antigens: (1) a nucleo-protein which is non-specific, as it is also formed from pneumococci; (2) a "type specific" protein corresponding to the particular type of streptococcus, and (3) a "species-specific" carbohydrate which is common to all hæmolytic streptococci and which, when linked to protein, acts as a specific antigen. Colonies of streptococci can be picked out when grown on media as a "matt" variety, which is virulent and contains the type-specific protein and an avirulent "glossy" variety which has lost the type-specific protein; but specific carbohydrate and the erythrogenic toxin were always present. This will indicate the complexity of the subject from the immunity point of view. The relation of streptococci to acute rheumatism is dealt with later.

SCARLET FEVER

(*Scarlatina*)

Scarlet fever is a contagious disease, characterised by fever, sore throat, a bright red eruption on the skin, and a tendency to certain complications, of which the most important are acute nephritis and otitis media.

Ætiology. *Scarlatina* is a toxæmia due to the toxins of a hæmolytic streptococcus (or group of streptococci) known as the *Streptococcus scarlatinæ* (6), of which four strains have been isolated. These streptococci can be isolated from the throat and tonsils of patients with the disease; they produce an "erythrogenic" exotoxin which has the property, when suitably diluted and injected into the skin, of producing an erythematous patch. This toxin is responsible for the rash and is also used for the *Dick test*, which is described later. If it is injected in large amounts into a susceptible individual a miniature attack of scarlet fever may be produced with vomiting, fever, furred tongue, generalised rash, circum-oral pallor, sore throat, and eventually desquamation. The same toxin may be produced from other strains of streptococci, for instance erysipelas, though it is usually most actively produced by the streptococci of scarlet fever. In addition to the rash the streptococci invade the tissues and produce the various complications such as otitis media etc., acting like any pyogenic organism.

Scarlet fever has been produced artificially by swabbing cultures of the *Streptococcus scarlatinæ* on to the tonsils of susceptible people, and the contagiousness of the disease is due to the discharge of the organisms in droplets of spray from the throat while talking and coughing. But the disease may be spread by means of clothing, books, papers, and other articles to which the virus clings with great tenacity, and by milk used as food. It may be caught from a patient suffering from a streptococcal sore throat, without scarlet fever (7).

The vast majority of those attacked by scarlatina are young children; it is comparatively infrequent in adults, and infants up to six months, having received immunity through the placenta, are insusceptible. Protection is not always perfect, so that some people have a second attack. Patients with open wounds and women in the puerperal state appear to be particularly susceptible to scarlatina, probably because the wound or the uterus provides an easy entrance for the virus. The disease in the surgical cases is often mild and not infectious, since there is no discharge from the throat. The rash is partial and of short duration, so that the connection with scarlatina was for a long time misunderstood.

Morbid Anatomy. The organs after death from scarlatina present little that is peculiar. In malignant cases there are the changes (*see* p. 18) common to the pyrexial and septic disorders. The tonsils present the conditions of ulceration or suppuration that have been observed during life, and there may be streptococcal invasion with inflammation of other parts.

Symptoms and Course. The period of *incubation* is one to eight days. Generally the invasion is sudden : the patient has a rigor, or vomits, and complains of frontal headache, with languor, pains in the back and limbs, and loss of appetite. The temperature rises to 103° or 104° , the pulse becomes very rapid, and the respiration is quickened. Very soon there is some complaint of sore throat, and swallowing is painful.

On the second day—that is, generally between twelve and thirty-six hours from the first symptom—the *rash* appears. It is first seen on the upper part of the chest, in front and on the sides of the neck, but soon spreads to the abdomen and back, and then to the upper and lower limbs. It consists of minute red spots, bright in the centre, fading towards the edge, and set closely together, so that the paler edges almost coalesce. Sometimes the coalescence is complete, so that the skin has a uniform bright red colour ; sometimes the eruption is more discrete, and areas of pale skin are visible between the spots. The face, forehead, and cheeks are, as a rule, deeply and uniformly flushed, without showing the punctiform arrangement of the rash which is seen elsewhere ; but the skin round the mouth remains pale, forming a sharp contrast to the cheeks (circum-oral pallor). With an abundant rash the skin becomes slightly swollen. The eruption presents many varieties as to depth of colour and distribution. It may be only pale pink, or it is deep, livid purple ; and in some severe cases papules may be raised above the surface, and may even vesicate or form minute points of pus ; and occasionally petechiæ occur. In its distribution the rash may be very limited, occurring only on the chest, or in patches on the thighs, elbows, or ankles, and this occurs frequently in second attacks, and in the mild cases sometimes seen in patients with open wounds, to which reference has just been made. The rash reaches its height on the third or fourth day, and begins to fade on the fourth, fifth, or sixth day ; altogether it may last from five to ten days. After the subsidence of the rash *desquamation* takes place—that is, the superficial layers of the cutis are shed. This occurs in the form of white, branny flakes on the sides of the neck, preceded (as pointed out by Caiger) by an appearance of pin-point depressions, due to the rupture of the epidermis at the top of each papule. This may be as early as the sixth or seventh day, while the eruption is still visible on the legs ; but the amount of epithelium that is shed and the size of the particles are very variable—sometimes there is nothing more than a little roughness about the tips of the fingers or toes, or in the folds of the palms of the hands ; while in other cases the epidermis peels off in large flakes, and in rare instances complete glove-like moulds of the hands and fingers are thrown off. Desquamation commonly takes from four to six weeks, but in these special cases a much longer time is required.

In the throat it is seen that the uvula, soft palate, and fauces are deep red, and often slightly œdematous ; the tonsils are reddened, swollen, projecting towards the middle line, and presenting a number of yellow points, from the follicles being distended or covered irregularly with ashy or yellowish secretion. In later stages they may suppurate, or sloughs may form in them. The nasal mucous membrane also inflames, and secretes a quantity of mucus ; and the submaxillary and cervical glands become enlarged and tender. The tongue is at first thickly covered with white fur, but in a few days this clears off from the tip to base, leaving a bright red, raw surface, on which the fungiform papillæ are unusually prominent, so as to give the appearance known as “strawberry tongue.”

During the course of the disease a temperature of 106° may be reached. With this the skin is pungently hot and generally dry, but profuse sweating may occur. The pulse rises to 120, 140, or even 160. The disease may reach its height about the fourth, fifth, or sixth day, and then, with the fading of the rash, the temperature begins to fall, generally subsiding rather gradually, but sometimes more suddenly, till the normal is reached, and convalescence is gradually established.

Complications and Sequelæ. These are numerous and important.¹ Not only the tonsils, but also the soft palate and the uvula, may slough. More frequently the *glands* under the jaw and in the neck are much swollen, and the subcutaneous tissue about them is infiltrated, becoming brawny and indurated. The skin then assumes a dusky red colour, and sloughing takes place beneath it, separating it from the subjacent tissues over a large area. Such cases are often fatal. During convalescence also *adenitis*, both *simple* (4·78) and *suppurative* (1·23), is likely to occur. Extension of the inflammation from the throat up the Eustachian tube may cause *otitis* (8·1), or inflammation of the ear, resulting in abscess of the tympanum, rupture of the membrana tympani and otorrhœa. This occurs most commonly in the first five years of life. In the course of the scarlatina this may seem of little importance; but it lays the foundation for serious or fatal results months and even years afterwards, among which may be enumerated suppuration of the mastoid cells, meningitis, abscess of the brain, thrombosis of the lateral sinus or jugular vein, with pyæmia as a result, hæmorrhage from the lateral sinus, and facial paralysis. Deafness on the affected side may of course happen, and a double otitis in a young child may be

FIG. 5.—Temperature in Scarlatina.

the cause of permanent deaf-mutism. Other local lesions may occur as sequelæ, for instance, sloughing of the cornea, abscesses in the subcutaneous tissues, or cancrum oris.

The kidney is often involved in connection with scarlatina, and nephritis and albuminuria may occur in the following three ways: *Albuminuria* is often present in the stage of rash and fever, small in quantity, temporary in duration, and probably arising in the same way as it does in severe cases of other infections (6·97). Secondly, *nephritis* (2·38) may be first recognised as a sequela from two to three or four weeks after the beginning of the illness, when the patient is quite convalescent or suffering only from desquamation. It then begins with a chill and rise of temperature and the passage of turbid brown or blood-coloured albuminous urine, the whole subsiding again without the occurrence of dropsy. In other cases the first thing noticed is some swelling of the feet and face, and then the urine is found to be scanty, high-coloured, and albuminous, with blood pigment and granular, hyaline and epithelial casts. Recovery from slight cases is common; but the dropsy may become general, and death may result after six, twelve, or eighteen months, with the severe secondary complications which will be described elsewhere (*see Nephritis*).

Broncho-pneumonia, *bronchitis*, *pericarditis*, and *endocarditis* occur from 0·1 to 0·4 per cent. in each of the cases, and *pneumonia*, *laryngitis*, *meningitis*,

¹ The bracketed figures in italics represent the percentages obtained from 21,006 cases in the Metropolitan Asylums Board's hospitals, Annual Report, Medical Supplement, 1914. No later series of figures has been published.

pyæmia, *chorea*, *jaundice*, and *cervical cellulitis* still less often. Pneumonia and broncho-pneumonia are responsible for one-eighth of the deaths. Broncho-pneumonia may be caused by inhalation of septic materials from the throat. *Pleurisy* (0.05) may happen as a sequela; and if effusion take place, it often becomes purulent quite early. As in other severe fevers, dilatation of the *heart* sometimes occurs. An acute general *arthritis*, which is probably identical with rheumatic fever, often follows upon scarlet fever so closely that the joints may be swollen when the rash is still present. It is generally known as *scarlatinal rheumatism* and may be a streptococcal manifestation, causing valvular disease, etc. It is often valuable as clinching the diagnosis in a doubtful case of scarlatina. Exceptionally the joints suppurate. About one-fourth of the published cases of *purpura fulminans*, itself a rare condition, have occurred as a sequela of scarlet fever. Some relations of scarlatina to *diphtheria* are mentioned under the latter (*see* Diphtheria).

Varieties. Besides the ordinary forms of scarlatina of moderate severity, which end in recovery, one recognises cases that are called *scarlatina maligna*. This form—the *toxic* form—includes severe cases, some of which are fatal within five or six days from the intensity of the disease without complication other than sore throat; but the mental faculties are dulled; delirium is frequent, especially towards night; and drowsiness and coma supervene. Sometimes the patient is struck down with convulsions and collapse, and dies in twelve or twenty-four hours before the rash has had time to develop. In other cases there are severe rigor and vomiting, early intense or livid rash, high fever and delirium; and the patients die in two or three days.

Cases with severe throat symptoms have been called *scarlatina anginosa*. To this nearly corresponds the *scarlatina ulcerosa* or *septic form* of Caiger, in which the faucial ulcers form a septic focus, from which the system may be poisoned.

The term *latent scarlatina* includes cases in which the rash and sore throat have been so slight as to escape detection, and the illness has only been discovered by the occurrence of desquamation or anasarca.

Diagnosis. Scarlatina is recognised, especially when the disease is known to be prevalent at the time, by the occurrence of feverishness with sore throat, followed in a day by the characteristic punctate erythematous rash. The other characteristic features that may help in the diagnosis are—the sudden onset often with vomiting, circum-oral pallor contrasting with the red cheeks, the state of the tongue, at first furred with a red edge, later patchy, and finally “strawberry,” pinhole-and-flake desquamation (*see also* p. 27).

In the early stage, when the presence of sore throat is the most prominent feature, scarlet fever is to be distinguished from diphtheria, tonsillitis, the anginous form of influenza, and secondary syphilis. When the rash has developed scarlet fever must be distinguished from measles, rubella (*see* p. 27), syphilitic roseola, typhus, and the “septic” rashes which may occur in puerperal fever and other septic conditions. Even quite insignificant septic foci, such as impetigo, may give rise to a scarlatiniform rash. Various drugs may also give rise to a rash resembling scarlet fever, and there are the rashes associated with intestinal disturbances from food or following the injection of horse serum. In these cases the skin may peel later.

The Schultz-Charlton blanching phenomenon provides a specific method of diagnosis: 0.2 c.c. of concentrated scarlatina antitoxin (1 in 10) is injected intradermally into an erythematous area; a blanching of the skin round the injection takes place in the course of ten to eighteen hours.

The Prognosis must be in all cases very uncertain. Even in the mildest cases, renal complications may be serious or fatal. The mortality, however, is variable, some epidemics being exceedingly mild, while in others the mortality may be 30 or 40 per cent. In the Metropolitan Asylums Board's hospitals in

1914 the mortality was 1·4 per cent., and in 1915 2·03 per cent. In individual cases the prognosis may have to be determined by the condition of the patient from day to day; complications increase the danger. Very severe angina and an intense or livid rash coming out late are unfavourable, and cases with sloughing of the cervical glands are generally fatal.

Preventive Measures. The period of quarantine is eight days. Isolation must be carried out at the earliest possible moment (*see* p. 11).

The frequency with which convalescent patients returning from fever hospitals to their own homes have conveyed the disease to their brothers or sisters, not till then infected, has given rise to the name *return cases* for the new sufferers. Since contagion is transmitted by secretions from the throat, nose, or ear, rather than by the desquamating skin, particular attention should be therefore directed to the former. Hence, while no patient should be allowed to mix with the unprotected till at least four weeks have elapsed, this period must be prolonged if there is still any sore throat or any discharge from the nose or ears. The final disinfection consists in the patient taking a warm bath and having his hair well washed. If in hospital he should be kept separate from other acute cases for some time before going home.

Susceptibility of individuals to scarlet fever is determined by means of the "Dick" test. 0·1 to 0·2 c.c. of a dilute solution of the toxic filtrate of the specific hæmolytic streptococcus is injected intradermally, the heated toxin being injected as a control into the other arm. A local area of redness, 20 to 30 mm. in diameter, beginning to appear in four to six hours, and reaching a maximum in twenty-four hours, indicates a positive reaction. Negative, pseudo and combined reactions are obtained as in the Schick test (*q.v.*). If scarlet fever breaks out in a children's ward, it is not necessary now to close the ward. The scarlet fever patient is removed to a fever hospital. All the patients are "Dick-tested," and on the following day all "Dick-positive" children are given a dose (5 c.c.) of scarlatinal antitoxic serum intramuscularly, then re-Dick-tested on the third day and a further dose of serum given if required (14). Unfortunately, the Dick test is not so certain as the Schick test in diphtheria.

Treatment. The administration of specific antitoxic serum during the first four days of the disease brings about a rapid recovery and prevents septic complications: 10 to 60 c.c. of concentrated scarlet fever antitoxin-globulins are injected; it has been injected intravenously, but a death was recorded (11).

The general treatment must be carried out in the same way as that of other fevers (*see* Pyrexia).

Local remedies to the throat are applied partly as palliatives, partly as antiseptics. The patient may be given ice to suck if the throat is painful. One of the most useful ways of applying remedies is by syringing. The patient lies on his side. The syringe is introduced nearly as far as the tonsil that is resting uppermost, the fluid being collected in a dish. Boric acid (half-saturated solution), or eusol may be employed. Where syringing is difficult swabbing may also be carried out, lotions of permanganate of potassium (2 grains to 3j), formalin (1 in 200), chinosol (1 in 600), the tincture of ferric chloride (3ss to 3j), carbolic acid (2 grains to 3j), boroglyceride, being applied every four hours with a brush or pledget of lint. In somewhat stronger solution they may be used as a spray. A useful solution for the spray consists of carbolic acid, 120 grains; iodine liniment, 2 drachms; rectified spirit, 1 drachm; water to 12 ounces. For pain or swelling in the neck and about the angles of the jaws hot fomentations or boric lint wrung out of hot water should be used.

Complications will require special treatment. Abscesses should be opened early. In otitis, relief of pain may be best obtained by applying small ice-bags to the mastoid regions, as the writer saw them used in Berne; hot fomentations and the gentle introduction of warm water into the meatus are less effective. If

suppuration of the middle ear is recognised, the membrana tympani may require puncture ; and the meatus may be gently syringed with warm water, or diluted Condy's fluid, or solution of boric acid (1 in 20). For synovitis salicylate of sodium should be given in 10- or 15-grain doses, and chloroform or belladonna liniment may be used locally. The prevention and treatment of scarlatinal nephritis will be considered hereafter (*see* Nephritis). In the severe typhoid forms, with quick, feeble pulse, stimulants must be given.

STREPTOCOCCAL SEPTICÆMIA

Ætiology. An acute septicæmia may arise at any time in the course of any localised streptococcal infection, or it may follow directly after the entrance of the streptococcus into the body. Thus doctors and medical students may become infected through accidental wounds sustained at operations and autopsies. Again a streptococcal septicæmia is a common form of puerperal fever, where the streptococcus gains entrance to the body from the uterus after childbirth.

Morbid Anatomy. The post-mortem findings in acute streptococcal septicæmia, apart from possible metastases, are not striking. The spleen will be large and soft ; there will be ecchymoses beneath the serous membranes ; the interior of the aorta and endocardium may be stained pink from hæmolysis, and there will be pin-point vegetations on the aortic cusps. Other changes described under Pyrexia may be present.

Symptoms. In *acute streptococcal septicæmia* the temperature may be hardly raised at all in extremely virulent and fatal cases. In other cases it may be continuous, remittent or intermittent, as shown in Fig. 1 (p. 18), with spikes sometimes reaching to 105° or even 106° F. Rigors are common and the pulse rapid. There are certain characteristic features. Diarrhœa is often frequent and troublesome ; the urine contains albumin, red cells and casts, while it may be definitely smoky—all signs that indicate that there is a streptococcal nephritis ; there is a rapidly progressive anæmia and emaciation and sometimes jaundice ; the tongue is raw or desquamated, and looks smooth and red (53). Then there may be some splenic enlargement, purpura and erythema, with evidence of the involvement of the lungs or mucous membranes. The peritoneum was involved in one case of the writer's. There may be a leucocytosis up to 30,000. The mental condition may be alert right up to the end, and is characteristically mildly euphoric in the subacute type. Polyarthritides, more commonly non-suppurative, is frequent (12 out of 31 cases) and pus may collect anywhere in the body ; the occurrence of these so-called "fixation" abscesses is a favourable feature, since the streptococci tend to become localised there. Fixation abscesses are not so common as in staphylococcal septicæmia.

The *subacute streptococcal septicæmias* are identical clinically with the various varieties of infective endocarditis ; in fact a case of streptococcal septicæmia running a prolonged course, but without the typical vegetations of infective endocarditis on the valves or walls of the heart, must be rare.

Diagnosis. The absolute diagnosis consists in isolating the streptococcus from the blood stream or from some localised lesion. The presence of a leucocytosis and a negative Widal will exclude typhoid. In most cases of pneumococcal septicæmia there will be some lung involvement and the respiration rate will be high.

Prognosis. This is a very serious disease, but recovery may occur even if the blood culture is positive. A high leucocytosis is a favourable feature.

Treatment. Intravenous injection of 30 to 60 c.c. polyvalent antistreptococcal serum may be used, or the same quantity of the concentrated scarlatinal antitoxin globulins. Surgical measures must be carried out as required.

ERYSIPELAS

(St. Anthony's Fire, The Rose)

Erysipelas is a specific contagious disease, characterised by a peculiar form of inflammation of the skin, and due to the invasion of a hæmolytic streptococcus.

Ætiology. The most common determining cause of erysipelas is the presence of a wound; and infection takes place through this breach of surface, and spreads to the surrounding skin. It affects infants and people over forty years of age more frequently than others; men and women are about equally prone to it. Some conditions of the individual increase the liability: chronic disease of the liver and kidneys, chronic alcoholism, and malnutrition from insufficient food. Cold and damp weather, overcrowding, bad ventilation, dirt, and bad food and water may act in the same way. There may be also an individual tendency, for it often recurs in the same person; at any rate, the immunity conferred by it seems to be short-lived.

Pathology. Microscopic examination of the skin of the affected part shows that the cutis and subcutaneous tissues are swollen, oedematous, and filled with large granular leucocytes, which in the upper layers of the cutis closely surround, as well as fill, the lymphatic vessels. The disease is spread through the superficial lymph spaces. It is often checked or stopped at lines where the skin is closely adherent to subjacent parts, as, for instance, along Poupart's ligament and the crest of the ilium.

Streptococci are found in the lymphatic vessels and lymph spaces at the advancing margin of the disease, as well as in the deeper layers of the skin of the central parts; and rabbits and human beings have been successfully inoculated from cultures.

Symptoms. Apart from injury and operation, erysipelas most commonly attacks the face, and the present description applies especially to that region. The *incubation* of the disease is probably only a few days—from three to six, or in some instances much longer. The *invasion* is generally by a chill or rigors and such malaise as commonly accompanies the onset of the specific fevers—headache, anorexia, furred tongue, and general pains. Within a few hours a red, tender spot shows itself on some part of the face: the side of the nose, the inner canthus of the eye, or the external ear. It may be determined by a lesion of the skin if this exists, and not infrequently it begins at the point of junction of the skin with the mucous membrane of one of the orifices—the nose, mouth, or external ear. The spot enlarges, and the skin becomes bright red, swollen, and very tender, and pits slightly on pressure. The inflammation may confine itself to one side of the face, but more often affects both, and may extend to the scalp. It spreads with varying rapidity, the advancing edge is sharply defined, thick, and raised above the surface, and small tongue-like projections can be felt under the skin in front, which is not yet reddened. The whole face may be thus covered in three, four, or five days. At the height of the disease the face presents a remarkable appearance: the features are enormously swollen, of bright or dusky red colour; the eyelids are distended so as to look like bladders; generally some muco-pus is oozing from between them; the ears are thickened and much enlarged, and the patient is absolutely unrecognisable; the scalp is also swollen and puffy. Often blebs form upon the cheeks or eyelids, which contain yellow sero-purulent or purulent fluid, and these may burst and leave yellow scabs, which further disfigure the patient. The lymphatic glands in the neighbourhood are enlarged and tender, and may be thus affected even before the beginning of obvious inflammation of the skin.

The disease is generally accompanied by high fever. The temperature generally rises early to 102° or 103°, and reaches a maximum of 104° or 105° on the third or fourth day. About the sixth day it tends to fall rather suddenly, but may remain high if the cutaneous inflammation persists, or may rise again with

any fresh outbreak of the local disorder. Indeed, it is closely dependent upon the inflammation of the skin ; in some cases, perhaps more often when the erysipelas is not extensive, the temperature may not rise above 102°. The pulse is quick and full, numbering 100 to 120, or more. The tongue is covered with a thick white fur. The urine is scanty, and in many cases contains some albumin, which may be present for some days. The inflammatory condition invades also the mucous membrane ; the palate, fauces, tonsils, and occasionally the laryngeal mucous membrane, may be reddened and swollen, and cause difficulties in respiration and deglutition. The blood shows a polymorphonuclear leucocytosis. Delirium is common in severe cases, and is generally of a low, muttering kind ; and coma may follow. While the inflammation is still advancing on one side, it may begin to subside at the points first affected. This receding edge is then less well defined, graduating both in colour and elevation into healthy skin, as contrasted with the advancing margin. The swelling, tenderness, and pitting on pressure subside in turn over the whole of the affected area ; the colour fades somewhat, but mostly changes to a brown tint ; and large, thick flakes of dead epidermis now begin to desquamate. This process may take some days. After erysipelas of the scalp the hair often falls out at the same time as the skin is shed, or somewhat later.

Death takes place from exhaustion, with delirium and coma, especially in older patients, habitual drinkers, and those with chronic visceral disease. It may also occur from complications.

Complications and Sequelæ. Abscesses may form under the skin, which may be due to secondary staphylococcal invasion, or the tense skin may slough, and induration, or rarely suppuration, of the lymphatic glands may ensue. The laryngeal œdema may cause asphyxia ; pneumonia and pleurisy are occasional complications, and peritonitis and endocarditis have been recorded. Pyæmia and meningitis have been frequently mentioned in connection with erysipelas, but both are rare as direct results of the erysipelas itself. The former may arise from the wound which preceded the specific inflammation ; the latter may occur if the original lesion has been a fracture of the skull, or if infection spreads inwards from the orbit. In erysipelas of the scalp, the delirium may be violent or maniacal, and accompanied by delusions, but of itself this is not sufficient to justify a diagnosis of meningitis. Mental disturbance may also be a sequela.

Diagnosis. Facial erysipelas may be confounded with erythema, acute eczema, herpes zoster, alveolar abscess, and even mumps. Erythema occurs in red patches, generally two or more in number, much less raised, and without pronounced fever. The vesications of an acute eczema and of herpes are distinctive, and herpes is unilateral and confined to one of the areas of distribution of the fifth nerve. Characteristic features of erysipelas are the spreading of the redness so that the maximum is always remote from the point of origin, the implication of the ear in the inflammation, and the great tenderness of skin in the advancing zone.

Prognosis. Though in most cases favourable, it is dangerous in proportion to the extent of surface involved ; and it is often fatal in old patients, and in the subjects of chronic visceral disease, alcoholism, or malnutrition.

Treatment. Since the infection spreads through the superficial lymph spaces of the skin, it may be arrested by contracting the spaces. This is carried out by painting non-flexible collodion in a ring outside the spreading edge. The application must be repeated several times a day as the collodion flakes off. Good results have sometimes followed the use of an antistreptococcal serum, injected subcutaneously in doses of 15 or 20 c.c. once or twice daily. Tepid or cold sponging may be resorted to where the fever is unusually prolonged or high. The diet should be light, easily digestible and nutritious, as in other febrile cases.

STAPHYLOCOCCAL INFECTIONS

Staphylococcal infections, though common enough, are by no means so common as streptococcal infections. They have a much greater tendency to localisation, so that while a staphylococcal septicæmia is uncommon, a staphylococcal pyæmia with metastatic abscesses is the rule, and when the disease is once established these pyæmic abscesses may keep on appearing in different parts for weeks or months, especially in the muscles, skin, or prostate. Like the streptococcus, the staphylococcus may invade any tissue of the body, and by far the commonest pathogenic variety is the *S. aureus*, though the writer does remember the case of a young man who had pyelitis with a highly ammoniacal urine, and *S. albus* was obtained consistently on cultivation. *S. aureus* readily gains admission to the body through the skin by means of gnat bites, scratches, etc., and local boils and whitlows, commonly result. Internally *S. aureus* is commonly responsible for cellulitis and osteomyelitis in young people where the infection begins on the diaphysial side of the epiphysial line, and otitis media. In adults abscess (carbuncle) of the kidney with perinephritis or perinephric abscess is more common. A staphylococcus arthritis is uncommon. The *S. aureus* tends to spread locally, so that a septic spot on the face may spread inwards, causing a local meningitis and a cavernous sinus thrombosis (16).

Staphylococcal Septicæmia. This is an even more serious condition than streptococcal septicæmia. When resulting from osteomyelitis it causes abscesses in the lungs and heart and a pericarditis. In another acute form there may be a meningitis so that organisms can be grown not only from the blood but from the C.S. fluid. For *treatment* injection of anti-staphylococcal serum may be tried (17), or in long-standing cases a vaccine. Abscesses may be opened, or they may be aspirated and filled up with flavine 1 in 1000.

PNEUMOCOCCAL INFECTIONS

The micro-organism first found by Sternberg in the saliva, and subsequently recognised by Fraenkel as the causative agent of acute lobar pneumonia, was called by him the *Diplococcus pneumoniae*; and it is otherwise known as the *Diplococcus lanceolatus*, and more generally as the *Pneumococcus*. It consists of oval Gram-positive cocci, of about 1μ in diameter, often united in pairs or in short chains of five or six. Each is surrounded by a distinct halo or capsule of colourless homogeneous material.

This organism is responsible for acute and severe inflammations in many organs and parts of the body, and is chiefly known in connection with acute lobar pneumonia, of which it is the cause in from 80 to 90 per cent. of the cases. However, it also attacks other organs. Thus there occur pneumococcal pleurisy, empyema, peritonitis, meningitis, arthritis, enteritis, endocarditis, pericarditis, nephritis, endometritis, and subcutaneous, intramuscular, and intravisceral abscesses. It is rather characteristic of pneumococcal infections that pus formation takes place relatively late, after a copious exudation of serous fluid. The pus, too, when formed often sinks to the bottom, leaving a fairly clear layer of serous fluid on top.

Four types of pneumococci have been isolated, which resemble one another morphologically and culturally, but have different biological characteristics. Types I. and II. account for two-thirds of pneumonia cases in this country and America, and anti-sera have been prepared which have been used successfully in treatment. Type III. occurs in the most severe cases, and the corresponding anti-serum is useless. Type IV. resembles the pneumococci found normally in the mouth, and is a mixed group containing those strains that do not conform to the other three types. It is of low virulence, and the resulting pneumonia is very mild.

Method of Typing. This can be carried out in a few minutes by mixing on a microscope slide the three standard diagnostic serums, Types I., II., and III., with a fleck of the sputum to be tested. The specimen is then examined with the dry lens ($\frac{1}{8}$ inch objective) and 4 ocular with substage condenser removed. The pneumococci, which are normally only just visible with this magnification, appear greatly enlarged in a positive reaction, the characteristic lanceolate pairs equalling in long diameter the size of a red blood cell. This apparent enlargement is the result of association of the pneumococcal capsular substance with the specific anti-body contained in the homologous serum, producing a change in the refractive index of the material surrounding the pneumococci which become conspicuous (24).

GONOCOCCAL INFECTIONS

The acute inflammation of the generative organs, male and female, known as *gonorrhœa*, is an infective disease, of which the micro-organism is the *Micrococcus gonorrhœæ* or *gonococcus*. The gonococci are found in the pus discharged from the urethra, and are largely contained within the leucocytes. They are decolorised by Gram's method.

The course of the disease, which is very variable, may be classified under five heads :

(1) *The Primary Focus.* Infection is, as a rule, by direct contact, and involves usually the urethra in the male, and the urethra, cervical canal, and, to a less extent, the vagina in the female. Gonorrhœa of the female genital organs is a fertile source of gonococcal conjunctivitis and other ocular lesions in the new-born infant.

(2) *Area of Local Spread.* The infection may spread along the lymphatics to the passages and organs in the neighbourhood of the primary focus, and may cause inguinal bubo, vesiculitis, epididymitis, orchitis, cystitis, prostatitis, pyelitis, endometritis, salpingitis and pelvic cellulitis and peritonitis.

(3) *Gonococcal Septicæmia*, i.e. a general blood infection without focal lesions. This is a rare condition, and in this sense the gonococcus resembles the staphylococcus, which rarely produces a pure septicæmia.

(4) *Metastatic Gonococcal Infection*, or focal sepsis. The spread of the infection from the primary focus to other parts of the body takes place by the blood stream. In severe cases there is also a general blood infection (septicæmia), as may be found in the more severe cases of gonococcal arthritis, or gonococcal endocarditis, which is one form of malignant endocarditis. However, in most cases the metastatic infection is not accompanied by a septicæmia.

The commonest infection of this type is the so-called *gonorrhœal rheumatism*, which includes arthritis, fibrositis, teno-synovitis, bursitis, myositis and perineuritis. Periostitis and osteo-myelitis are rare. The eye is not uncommonly affected by metastatic infection, the principal lesions being iritis and conjunctivitis. It is probable that some cases of "simple" mitral disease are secondary to gonorrhœa. There is a gonococcal pleurisy.

Gonorrhœal rheumatism, from its resemblance to acute rheumatism, requires separate notice. It begins at an interval of fourteen days or three or four weeks from the commencement of the urethral discharge, sometimes while the discharge is still purulent, more often during the subsequent stage of gleet.

Morbid Anatomy. There are serous effusion into the joint, infiltration and œdema of the tissues around it, and in severe cases suppuration, erosion of the cartilages, disorganisation of the joint, and ankylosis. The synovial membrane is primarily affected in the acute cases, and the surrounding fibrous tissues are chiefly and first involved in the subacute forms.

Pathology. The gonococcus has frequently been found in the fluid of the

inflamed joints and of the sheaths of the tendons when they are affected. If suppuration takes place, pyogenic organisms may also be present. In more chronic cases the gonococcus is not found. It may be tucked away in the recesses of the joint. Another suggestion is that the inflammation is due to the gonococcus toxin.

Symptoms. In *acute* forms of gonorrhœal rheumatism several joints are at first affected with pain and swelling, but the disease often, after a time, localises itself in one only, which may be the elbow, knee, ankle, wrist, or foot. There is very extensive redness, with swelling, pain and tenderness. The redness often spreads up the limb far beyond the joint, and the tissues are infiltrated to a corresponding extent. This infiltration may be actually mistaken for abscess, and it may also have a closer resemblance to gout than to rheumatic fever. The pain is very severe on the slightest movement; the fever is not high. The inflammation only slowly subsides, and leaves a good deal of stiffness behind; but the joint does not often suppurate. Cardiac complications are only occasionally observed. The late N. C. Davies-Colley stated that this form of gonococcal arthritis was as common in women as in men.

In other less acute or *subacute* cases the resemblance to a mild rheumatic fever is in some respects closer; the joints are swollen, not so red, and less generally infiltrated. All the joints in the body may be affected; but the knees, ankles, and wrists are most often involved. Not infrequently there is much pain in the fasciæ, especially in the plantar fascia, and the sheaths of tendons may be involved. Spondylitis occurs in a certain proportion of the cases. As in the acuter forms, the inflammation tends to be persistent and does not readily subside and come again, as it does in ordinary rheumatic fever. It lasts two, three, or more weeks, and leaves a great deal of stiffness or even fibrous ankylosis.

Diagnosis. The disease is most likely to be mistaken for *rheumatic fever* until it is discovered that the patient has a discharge, or until the persistence of the arthritis in a few joints makes one suspect the nature of the case. The resemblance may be increased by a history of previous attacks, for, though gonococcal synovitis does not itself recur after long intervals like rheumatic fever, other attacks are often induced by fresh infection. The acuter forms of the disease may closely resemble *erysipelas*, *abscess*, or *acute gout*. The age of the patient and the position of the inflammation will generally exclude the latter. *Pyæmia* may be a cause of multiple synovitis after gonorrhœa; but in this case the illness is generally more severe, with rigors and such serious complications as pericarditis, endocarditis, pneumonia, or pleurisy.

An investigation of the common vulvo-vaginitis of children up to 15 years has shown that 36 per cent. are gonorrhœal, and 64 per cent. are non-specific and due to staphylococcus (51).

Treatment. It is, no doubt, desirable to cure the urethral discharge as soon as possible. For the arthritis alkalis and iodide of potassium have been largely employed, the latter in full doses; but it is probably better to give plenty of good food, with cod-liver oil and iron or cinchona. Vaccine treatment is also employed. Autogenous vaccines are obtained by cultivating the gonococcus from the patient's discharges, and may be injected repeatedly. But the cure often takes five or six weeks. Stock vaccines are prepared from a number of different strains, and not from the patient's own organisms. Recently sensitised and detoxicated vaccines have been used. The former is a mixture of a vaccine with antigonococcal serum. The latter is a vaccine with the virus much attenuated, either by treating the organisms with *caustic soda* or by prolonged cultivation on *artificial media* outside the body. Locally the joints may be painted with iodine. In acute cases the limb should be kept completely at rest by means of a plaster of Paris splint; and anodyne applications, especially the compound mercury ointment, with extract of belladonna, may be used. As soon as the inflammation has subsided the tendency to fixation must be met by friction, massage, and passive movements.

CEREBRO-SPINAL FEVER

(Cerebro-spinal Meningitis, Spotted Fever)

This disease was first recognised at Geneva in 1805. Since 1860 it has been prevalent in the United States and in Germany. In 1846 it appeared in Ireland, and again in a severe form in 1866-68; and in 1906-8 some hundreds of cases occurred in Glasgow and in other towns in Scotland, and a few in London. The disease is endemic, sporadic cases occurring, especially in infants. In the latter the disease used to be described as *posterior basal meningitis*. Every now and then the disease assumes epidemic form. This occurred in this country in 1915 and 1916.

Ætiology. The specific organism is a diplococcus (*D. meningitidis intracellularis* of Weichselbaum or *meningococcus*), which is seen in the polymorphonuclear leucocytes of the meningeal exudations, but also lying free between the cells; it is also sometimes found in the blood, in pus from the joints, in pneumonic foci in the lungs, and in the mucus of the naso-pharynx. Meningococci when tested by their agglutination reactions fall into two main groups; they are sometimes called meningococci and parameningococci. Each group is again divisible, also by agglutination, into a number of different strains. As far as their cultural characteristics are concerned, the different groups cannot be separated from one another, and there is not much evidence that they produce different symptoms. Meningococci may be found in the naso-pharynx of perfectly healthy people, who are known as *carriers*. It is possible that the meningococci latent there assume a virulent form from time to time so that an epidemic breaks out. It is noteworthy that carriers do not very often themselves contract the disease; but they disseminate the organisms by projection of their saliva in talking and coughing, so that susceptible people become infected by inhalation and get the disease. Normally about 5 per cent. of the population are carriers; when the number reaches 20 per cent. an epidemic may break out. An epidemic does not sweep through the community like influenza; it is only people here and there who contract the disease. Previously the young have most often been sufferers, 80 per cent. of cases being under sixteen, and the most susceptible age of all being from birth to five years. This tendency was not shown in the 1915-16 epidemic. As a rule the sexes are attacked nearly equally. The disease is usually more prevalent in the winter months; it is probable that overcrowding, such as occurred among the troops at the beginning of the War, and the presence of catarrhal throat affections, owing to sneezing and coughing, tend to its dissemination.

Pathology. Much discussion has taken place as to how the meningococcus obtains access to the meninges. The older view that it spread direct to the brain from the naso-pharynx *viâ* the sinuses or the cribriform plate has received some support from the finding of pus in the sinuses at post-mortem. However, in many cases suppuration of this kind has not been found although carefully looked for. On the other hand, the meningococcus was isolated from the blood and from skin lesions before the onset of meningitis in cases during the last epidemic, so that, as in other septicæmias, the meninges were probably infected *viâ* the blood stream, the naso-pharynx being the primary focus.

A third view has been recently expressed (28), viz., that infection passes from the blood to the choroid plexuses and then to the intraventricular fluid. The normal passage of the fluid carries it through the roof of the fourth ventricle out to the subarachnoid space, while there is a special tendency for the inflammatory products to accumulate at the periphery where the fluid is normally absorbed, i.e. at the superior longitudinal sinus, and in the spinal canal. The evidence for this is: (1) That in fulminating cases meningococci are found in the ventricles alone, while there is no perceptible inflammation of the meninges, but

there is acute inflammation of the choroid flexures ; (2) In less acute cases the fluid from ventricular puncture, though it has the same composition as fluid from lumbar puncture, always contains fewer pus cells, suggesting that these have accumulated at the periphery. In favour of this view, it has been shown in dogs that Indian ink, when injected into the ventricles, travels from the fourth ventricle upwards in the subarachnoid space along the sulci, resembling the distribution of pus in meningitis.

Morbid Anatomy. There is an acute lepto-meningitis of the brain and spinal cord. The pus and lymph are abundant at the base of the brain, in the quadrilateral space and on the convexity, along the larger blood vessels and in the fissures. In the spinal cord the posterior surface is more affected than the anterior, and the lumbar region more than the other parts. The ventricles of the brain contain turbid serum or pus. In the early stages they are reduced in size, owing to œdema of the brain substance. Punctiform hæmorrhages, accumulations of leucocytes, or actual abscesses are found in the cortex of the brain. Other changes found are congestion of the lungs, liver, spleen, and kidneys, fatty degeneration of the renal epithelium, and granular degeneration of the voluntary muscular fibres, sometimes ecchymosis of the pericardium and pleura and suppuration of the joints. In fulminant cases there is often hæmorrhage into the adrenals. In cases of long duration pronounced hydrocephalus is present, and the pia-arachnoid has an opaque appearance, as if flour had been dusted on its surface. This is due to increased connective tissue formation, the result of the previous inflammation. The hydrocephalus is due to the sealing up of the outlets of the cerebro-spinal fluid round the base of the brain (foramina of Majendie and Luschka), because during the acute stage pressure is exerted at this spot by the swollen brain being forced down into the rigid foramen magnum. In infants suppurative meningitis is sometimes found on the vertex of the brain as well as at the base, while at other times the vertex is free and the base and spinal cord alone affected. It is this latter condition that has caused the disease to be known as "posterior basic meningitis."

Symptoms and Course. The incubation period may be as short as one or two days, but it may also be much longer. The disease itself is extremely variable, so that many different clinical forms have been described. There are, however, two chief phases : (1) the general blood infection ; (2) the localisation in the meninges, which usually follow one another in this order. The following is Rolleston's classification :—

1. The *fulminating* type ; this is usually fatal within forty-eight hours. It may begin with maniacal symptoms, or the patient may suddenly become unconscious. Again, from the outset there may be collapse, vomiting, and severe headache, and sometimes diarrhœa and a purpuric eruption with large hæmorrhagic areas. There may be no meningitic symptoms at all, the patient remaining fully conscious to the end. In other cases coma rapidly comes on.

2. The *acute* form begins suddenly like an attack of influenza with headache, fever, vomiting, and, especially in children, with convulsions. Meningitic symptoms appear within a few hours ; there is stiffness of the muscles of the back of the neck, which may be shown by attempting to bend the head forwards, and often the head is drawn back by the contraction of the deep muscles ; the dorsal and lumbar muscles may be similarly affected, so that the back is kept straight (*orthotonus*), or even arched with the concavity backwards (*opisthotonus*) ; and sometimes the legs and arms are flexed in tonic spasm. Pains frequently extend down into the muscles of the lower extremities, and cutaneous hyperæsthesia may be also present. The knee jerks are often active, but may be absent ; Kernig's sign is practically constant. There may be, in different cases, ptosis (3.6)¹ or strabismus (25) ; usually dilatation, or inequality of the pupils ;

¹ The bracketed numbers in italics indicate roughly the percentage of cases in which the particular symptom occurs. These percentages vary greatly in different epidemics.

or contraction of the facial muscles; but trismus is rare. Optic neuritis (10), and conjunctivitis (5-6), and panophthalmitis (1-4) occur. Pain in the ear, tinnitus and defective hearing are not uncommon, and suppuration of the labyrinth or of the tympanum may occur. Deficiency of the sense of smell has been noted. Drowsiness, delirium, and coma, sometimes with Cheyne-Stokes breathing, or convulsions, supervene in due course; and death takes place with varying rapidity in different cases. Fever is present from the first, but it runs no regular course; it is remittent or intermittent, perhaps normal for a day or two, and then rising to 102° or 103° , seldom exceeding 104° . Occasionally the fatal termination is preceded by a temperature of 108° or 109° . With recovery the temperature falls slowly and irregularly. The pulse is variable. An important feature of epidemic meningitis is the occurrence of cutaneous eruptions; the earliest to appear are rose spots, papules, or petechiæ, which are due to emboli in the septicæmic form of the disease; herpes facialis, which is usually regarded as the commonest rash (50), occurs about the fourth day; herpes zoster is much rarer. The rashes may be present together. Sometimes the joints are inflamed, hot, red, painful, and swollen, due to synovitis (10)—a condition which generally subsides, but may go on to suppuration. The abdomen is often retracted; the spleen is not often enlarged. The urine may contain a little albumin, or a trace of sugar. Epididymitis and orchitis, bronchitis, pneumonia, pleurisy, endocarditis, and latent pericarditis sometimes occur. A leucocytosis of from 15,000 to 60,000 is constant, and is nearly always polymorphonuclear; only occasionally in infants and young children is there a lymphocytosis. If a lumbar puncture be performed the fluid withdrawn may be clear in the early stages, but is usually turbid and may be purulent; it comes out under an increased pressure of from 150 mm. to 500 or 600 mm., and its quantity may reach 20 or 30 c.c. It contains increased quantities of albumin and globulin, and shows in acute stages polymorphonuclear leucocytes, which contain the *meningococcus*. The organisms may also be free in the cerebro-spinal fluid. In chronic cases lymphocytes may sometimes be present in excess.

3. The *abortive* forms are of two kinds: (A) those cases which do not progress further than the septicæmic stage and then get better within twenty-four or forty-eight hours before the meningeal invasion; (B) mild cases with both kinds of symptoms. Relapses or recrudescences are apt to occur in abortive cases.

4. The *chronic* forms: (1) Purely septicæmic, and not often recognised, may last for weeks with periodic rises of temperature resembling malaria, joint pains, orchitis and various skin rashes; sometimes it follows a definite meningitic attack. (2) *Encysted and loculated meningitis*, due to the shutting off by adhesions of some of the space containing cerebro-spinal fluid. This type occurs, particularly in infants, as a sporadic disease, and was known previously as *posterior basilar meningitis*. It is distinguished from most adult forms by—(a) the chronicity of the disease; (b) the rarity of skin eruptions; (c) loss of vision quite early in the disease without visible retinal changes or optic neuritis; (d) the rarity of deafness: there is often hyperacuity, the child screaming at the slightest noise; (e) the prominence of opisthotonus owing to the flexibility of the spine; (f) the bulging of the fontanelle from increased intracranial pressure; (g) Kernig's sign is rather inconstant at first, but it usually occurs late in the disease. The course is most variable; the child may lie semi-conscious for weeks, at first well nourished, but later it begins to waste. Complete recovery may take place, or hydrocephalus, cerebral diplegia, mental deficiency, or deaf-mutism may result.

Diagnosis. This is not difficult in the course of an epidemic. The characteristic features are the sudden onset, the headache, vomiting, pain in the back and limbs, stiff neck, and the herpes labialis. The purpuric eruption also seems to distinguish it from tuberculous and other forms of suppurative meningitis,

e.g. pneumococcal, influenzal, streptococcal, etc., which must always be carefully considered. Obscure toxic conditions, such as those arising from some kinds of food poisoning, have been mistaken for the disease. It is desirable in all cases to perform lumbar puncture, and prove the nature of the disease by microscopic examination, or by culture, of the meningococcus. In the later stages of the posterior basal form, the organisms may not be seen in the fluid, and lymphocytes may replace the polymorphonuclear leucocytes. The organism may also be cultivated from the blood in the early stages. Intra-ventricular puncture has also recently been used in diagnosis (28). In infants fluid may be obtained through the anterior fontanelle. In adults Goetze's channel borer is used for piercing the cranium on the vertex either 1 cm. or 4-6 cm. from the middle line.

Many diseases have been at different times confounded with cerebro-spinal fever, especially in early stages, such as pneumonia, influenza, and measles. Acute poliomyelitis, in its so-called meningitic form, may closely resemble it; and the diagnosis may be only possible after a lumbar puncture.

Prognosis. The mortality has varied from 20 to 90 per cent. in different epidemics, but is rarely below 50 per cent. in untreated cases. The disease is most fatal during epidemics among infants, and in the fulminating cases. With efficient serum treatment the mortality has been diminished to 18 per cent. The impression was gained from the last epidemic that, apart from deafness, the patient, if he survived, was not likely to suffer from permanent disability.

Prevention. After the disease has appeared in the military and naval forces and institutions where there is crowding, it is now considered useless to segregate contacts, since the carrier rate is equally high among the contacts and the remainder of the men. The best plan is to space out the beds, improve ventilation, prevent indoor crowding in canteens, and possibly treat carriers with a fine spray containing 1.5 to 2 per cent. zinc sulphate. An oily spray might be used (29). A case has been made out for protective inoculation with a stock vaccine during an epidemic.

Treatment. Apart from general treatment applicable to any pyrexia, the treatment consists in withdrawing cerebro-spinal fluid to relieve pressure and in injecting antimeningococcal serum. It is essential to give the serum corresponding to the particular strain of organism, and when this is not known, as, for instance, at the beginning of the attack, a multivalent serum may be given. The sooner the serum is administered, the better is the prognosis. At the very beginning of the attack in the septicæmic stage doses of 20 to 40 c.c. are injected intravenously until 200 to 600 c.c. have been given in all. In the meningitic stage the serum is given both intravenously and intrathecally (30). Since the present multivalent serum is weak it has been suggested that an initial dose of 100 to 200 c.c. should be given intravenously, and this is repeated in forty-eight hours if there is no clinical improvement. Lumbar punctures are repeated at twenty-four or forty-eight hours' interval; the cerebro-spinal fluid which is under pressure is allowed to run out through the lumbar puncture needle, and the serum should be allowed to run in slowly in less amount than the amount of fluid removed. Twenty to thirty cubic centimetres are given twice daily for three or four days, and the foot of the bed is raised to allow it to run down towards the brain. After the serum treatment is finished, a raised cerebro-spinal pressure should still be relieved by lumbar puncture at intervals of one to several days. If the fluid does not run freely *cisternal puncture* should be carried out. In a recent case of the writer's—a girl aged six—eleven lumbar punctures and fourteen cisternal punctures were required over a period of forty days and recovery was then complete. Irrigation of the theca with normal saline or 3.8 per cent. sodium citrate has been of value in preventing adhesions. Where adhesions have formed and the intracranial contents are shut off, the lateral ventricles may be tapped and serum injected. In young children this can be carried out through the anterior fontanelle.

*Bacterial Diseases—II. Bacillary***DIPHTHERIA**

Diphtheria (from *διφθέρα*, a prepared hide, piece of leather) is an acute infectious disease, of which the essential clinical feature is a peculiar inflammation of surface tissues resulting in the formation of a so-called "membrane." This commonly affects the mucous membrane of the mouth, pharynx, nose, or larynx, more rarely some other mucous membrane (conjunctiva, vagina), or the abraded skin, or the surface of a wound.

The specific micro-organism of diphtheria is the bacillus described by Klebs and Loeffler. It is a non-motile rod, varying in length in different circumstances, from 2.5μ to 6μ . It is slightly curved, and often clubbed at one end. It is Gram-positive and shows "beading" with Loeffler's methylene blue. The *B. diphtheriae* is found for the most part in the deep layers of the diphtherial membrane, but may be present in small numbers in the lymph glands, and in the liver, spleen, and kidneys.

Ætiology. Diphtheria is contagious, being conveyed directly, as in kissing, or by means of droplets of saliva, projected into the air as the result of coughing or talking, as well as by clothes and other objects. The bacillus survives drying, and has been found in the dust of the sick-room, and there is evidence to show that it may be sometimes transmitted over considerable distances of country by the wind. Milk is a well-known channel of infection; but this is due to human contamination, and not to any disease of the cow. Water sewage and sewer gas are not known to be vehicles of infection.

The *diphtheria-carrier* is also a source of contagion. In one-eighth of convalescent cases the bacillus is found in the throat for one or two months after the first symptom, and in a few cases for three or four months (*convalescent carriers*). From 8 to 30 per cent. of those in contact with a case of diphtheria become *contact carriers*; but in the later periods of the infection the bacilli have often lost their virulence, and in any case a carrier is not necessarily an active source of contagion. Diphtheria bacilli have been found in 10 per cent. of Baltimore school children. These were classified as *healthy carriers*, as only a very small proportion had ever been in contact with a case of diphtheria. In the majority of these healthy carriers, the bacilli disappeared in a few weeks without treatment. They were non-virulent, and remained so when inoculated into the throats of five healthy persons. Virulence can be tested by inoculating a guinea-pig, and from these experiments it would seem advisable to make this test before deciding to isolate and treat diphtheria carriers.

Diphtheria sometimes complicates measles and scarlatina (about 2 per cent. of each at the M.A.B. hospitals); it is more frequent in rural than in urban districts, especially in the more exposed parts of the former; and it affects both sexes and all ages, but it is especially frequent in children up to ten or twelve years of age. Its maximum incidence is in October and November.

Pathology. The inflammatory change which is characteristic of diphtheria is the formation of a "false membrane." It is the combined result of necrosis of the superficial tissues and the exudation of fibrin and leucocytes. A membrane which does not extend beyond the base of the epithelial layer is called a "croupous" membrane, and can easily be pulled off without bleeding. This is the case in the trachea in diphtheria, where it consists chiefly of fibrin and leucocytes, and is loosely attached to the surface. In the fauces, on the other hand, the stratified epithelium is infiltrated with fibrin as well as the subepithelial connective tissue, and necrosis takes place, causing the formation of a greyish white or white layer firmly adherent to the deeper tissues. This is called a "diphtheritic" membrane. It is difficult to remove and leaves a bleeding surface. In the smaller bronchi the exudation is purulent; the lungs often present lobular pneumonia, with occasional hæmorrhages.

Diphtheria toxin has a profound effect : (1) On the *circulation*, causing a fall in blood pressure and concentration of the blood, the percentage of hæmoglobin being greatly increased. The plasma passes out into the tissue spaces. In fatal cases the cells of the suprarenals show chromatolysis (Harding). (2) On *nerve fibres*, causing disintegration of the myelin sheaths and rupture of the axis cylinders. Degeneration of anterior horn cells has also been described. The toxin primarily attacks the nerves locally, and this explains the fact that paralysis of the palate is such a common accompaniment of faucial diphtheria. Similarly in wound diphtheria the paralysis affects the muscles in the neighbourhood of the wound (Walshe). It is possible that it passes up the nerves to the central nervous system, like tetanus toxin and the virus of hydrophobia.

It is remarkable that in *laryngeal diphtheria* this toxic action is not very noticeable. Possibly this is due to the membrane being "croupous" in character, so that toxins are not readily absorbed.

The changes in the various organs are attributable to the influences of the toxins circulating through the body. The heart may be pale, soft and friable ; the muscular fibres show a cloudy swelling and fatty changes, and blood is extravasated. The convoluted tubules of the kidney show fatty degeneration, and the epithelium is in many places separated from the basement membrane.

Streptococci and staphylococci are often present in the superficial layers of the diphtherial membrane, and sometimes lead to secondary suppurative lesions.

Symptoms and Course. The *incubation* is two to ten days.

Faucial Diphtheria. The disease, though febrile, begins insidiously ; there are generally malaise, loss of appetite, and headache, and there may be nausea, vomiting, or shivering. Sore throat is soon complained of, and it is seen to be inflamed. Within a short time one or more patches of a creamy white deposit form on the inflamed surface. There are *five* areas where such patches occur in diphtheria, between the pillars of the fauces on both sides, *i.e.* over the tonsils (2) ; the uvula (1) ; the soft palate on both sides (2). It is characteristic that there is never more than one patch in a particular area, but any number of the areas may be affected at the same time. The patch is raised above the surface of the mucous membrane, and the edges are sharply defined ; the colour may be glistening white, bluish, yellow, or grey. Coincidentally with the inflammation of the throat the lymphatic glands at the angle of the jaw enlarge, and they can always be felt on one or both sides, according to the lesions within. Sometimes the typical membrane is preceded by a grey mucous secretion. Gangrene occurs occasionally in the severe cases.

The temperature of diphtheria is very variable, and runs no definite course ; it may rise to 103°, 104°, or 105°, but is often throughout the whole illness much lower. The appetite is lost, and feeding becomes difficult and painful from the condition of the throat. In a large proportion of cases, variously estimated at 25 to 60 per cent., the urine is albuminous, and this occurs, not after the illness, as in scarlatina, but during the height of the throat symptoms. In some cases the specific inflammation spreads to adjacent mucous membranes—those of the nose and the conjunctiva, the Eustachian tube (causing otitis media), and the larynx and respiratory passages. Severe cases may be hæmorrhagic in type with epistaxis, bleeding from the throat and subcutaneous ecchymoses. Apart from these complications, there may be cardiac failure with death at the beginning of the disease ; but the characteristic feature is a gradual fall of blood pressure which begins at the end of the first week, reaching a maximum between the eighth and twelfth days and disappearing in twelve to twenty-two days. This hypopæsia is responsible for 50 per cent. of the deaths in the first three weeks ; it is accompanied by vomiting without pain, continuous air hunger, sighing, extreme restlessness when the systolic blood pressure is below 60 mm., and is proportional in amount to the severity of the disease in the early stages. The pulse rate, size of heart, apex beat, first beat sound, are normal and the pulse is regular (22).

Nasal diphtheria may occur alone, or as the result of a direct spread from the fauces. There is more or less obstruction to nasal respiration, the mucous membrane is swollen, and a muco-purulent or thin pale brown mucoid secretion runs from the nostrils, reddening or excoriating the alæ and adjacent upper lip. It may be streaked with blood, or decided epistaxis may occur.

Laryngeal diphtheria presents the symptoms of laryngitis, and the obstruction, due to the swollen mucous membrane, is increased by the presence of the diphtherial false membrane. It is rare in adults.

The *first stage* is indicated by the presence of a loud, brassy cough and a rough, hoarse voice, and it lasts for at most two days.

In the *second stage* there is respiratory distress with cough and aphonia. Stridor develops owing to narrowing of the glottis, being most marked during inspiration. As obstruction increases the supra-clavicular, supra-sternal, and intercostal spaces are sucked in with each inspiration; and in infants and young children with soft yielding bones the lower end of the sternum, or the three or four lower ribs, are drawn in, showing the extent to which the air is hindered from access to the lungs through the glottis. Slight degrees of obstruction may persist some days without much change, but more often the case gets progressively or rapidly worse. The face, at first flushed, with bright eyes, gets cyanosed. The child is restless, putting its hand to its mouth or throat, as if to remove the impediment. The cough becomes husky, and from time to time there may be spasmodic closure of the glottis, in which violent inspiratory efforts are made, and the cyanosis becomes extreme.

In the *third asphyxial stage*, which only lasts a few hours, the pulse becomes weaker, and the respiratory effort is lessened. The skin is livid, the extremities are cold, the mental faculties are blunted, and stupor supervenes. Sometimes there are convulsions before the end.

As a rule, in laryngeal diphtheria the process is not confined to the larynx; it spreads to the trachea and the bronchi, forming a continuous membrane in the former, which, in the middle-sized and smaller bronchi, is gradually changed into a purulent secretion. These morbid products naturally increase the difficulty of breathing, though it is not always easy to recognise their presence by physical signs; in fact, death not uncommonly occurs from blocking by a plug of desiccated mucus or loose membrane at or below the bifurcation of the bronchi after a successful tracheotomy (Biernacki). Generally a loud and stridulous noise is heard in the chest, caused by the obstruction at the glottis. It may be mixed here and there with mucous râles, and there may be patches of tubular breathing, due to the broncho-pneumonia which is so frequent a result of the spread of diphtheria into the lungs.

Laryngeal diphtheria is often primary, though there is usually some catarrh of the throat, but it may be associated with faucial and nasal diphtheria.

Complications and Sequelæ. Complications are chiefly the extension of the disease to different parts, which have been described.¹ *Pleurisy* may accompany the *pneumonia* (0·3), or *broncho-pneumonia* (1·0). *Albuminuria* (23·3) is rarely more than a symptom, but occasionally a definite nephritis (0·7) may persist or occur as a sequela. The lymphatic glands may inflame and suppurate or slough with about one-third the frequency of occurrence in scarlet fever; thus *suppuration* in the acute stage (0·2), in convalescence *simple adenitis* (2·1), and *suppurative adenitis* (0·6).

The most important sequel of diphtheria is the affection of the peripheral nerves, which results in *diphtherial paralysis* (8·8). This shows itself first in the soft palate. Some days, or a week, or several weeks, after apparent recovery, the child is noticed to speak with a nasal, twanging voice, and when it swallows liquids a small quantity is regurgitated through the nose. These defects are due

¹ The bracketed percentages in italics are from 6,184 cases in M.A.B. hospitals in 1914.

to paralysis of the soft palate, which fails to shut off the mouth from the nose, as it should during speaking and swallowing. Shortly after this the child is noticed to be weak in the legs, and unable to walk any distance, or the knees give way on standing for a short time. The knee jerk is lost quite early. In older children and in adults failure of accommodation of the eye for near objects is often noticed, due to paralysis of the ciliary muscle; and the extrinsic muscles of the eye may be also affected, producing strabismus or squint. In many cases the paralysis does not proceed beyond this stage, and in a few weeks the muscles recover their power completely. In others the muscular system throughout the body may be affected. The patient lies motionless in bed, respiration is rendered difficult from paralysis of the intercostal muscles or diaphragm, and food given by the mouth is rejected, from inability to swallow it. The paralysis of the diaphragm is often followed by collapse of the lower lobes of the lungs (*see* Lesions of the Phrenic Nerve). The laryngeal muscles are also sometimes affected—one, or many, or all of them. Thus there may be paralysis of one cord, or paralysis of the abductors, or paralysis of all the muscles, with cadaveric position of the cords. The voice in the last case will be lost completely, and variously modified in other cases (*see* Paralysis of the Larynx).

Sensory symptoms may occur, but in children they are frequently not detected. They consist in a feeling of numbness, or formication, or distinct anæsthesia, especially in the extremities. Ataxy has been observed with very little actual paralysis, and rarely transient muscular spasms. Sometimes the muscles or the nerve trunks are tender on pressure. In severe cases electrical reactions are diminished, and some muscular atrophy ensues. Recovery generally takes place within three or four months, and the paralysis rarely, if ever, becomes chronic. Death, however, results sometimes from paralysis of the diaphragm, with gradually increasing accumulation of secretion in the bronchial tubes, and sometimes from cardiac paralysis, shown by a feeble, irregular or intermittent, generally quick, but sometimes slow, pulse, with vomiting and cyanosis.

Diagnosis. *Faucial Diphtheria.* The cardinal features are—insidious onset; characteristic membrane already described; relatively slight pyrexia; lowered blood pressure and weak pulse; albuminuria; onset of paralysis. The diagnosis can only be positively established by the bacteriological cultivation of the Klebs-Loeffler bacillus from the secretions of the affected part. This is generally done by means of a swab of cotton wool on the end of a piece of wire: the swab is smeared over the fauces or tonsil, inserted in a sterilised glass or metal tube, and sent to the bacteriological laboratory for cultivation. It is important to remember that bacilli are sometimes cultivated from the throat, both together with the Klebs-Loeffler bacillus and apart from it, which resemble it closely, but, unlike the *B. diphtheriæ*, are not virulent to guinea-pigs. The most important of these is *Hofmann's bacillus*, which is often found. It is about 2μ in length, and generally arranged in pairs.

In *follicular tonsillitis* small yellow, sometimes white, plugs are seen; they can be easily removed. There are often several plugs in the same area, as contrasted with one patch in diphtheria. The temperature is usually high. The tonsillitis and pharyngitis of *scarlatina* must also be considered, and also influenzal sore throat, herpes, and secondary syphilis. *Vincent's angina*, which is described under Diseases of the Throat, resembles diphtheria in its membrane.

Laryngeal Diphtheria. The diagnosis will be easier if there is simultaneous faucial or nasal diphtheria. It must be distinguished from catarrhal laryngitis, which may be simple, or may herald the onset of measles. Clinically it is often impossible to distinguish the two, so that a swab must be taken at the earliest opportunity. It is safest to assume the case is one of diphtheria until the contrary has been proved. Laryngeal diphtheria must also be distinguished from (a) obstruction below the larynx, such as broncho-pneumonia where there may be recession of the ribs, but not aphonia; and pressure from enlarged glands;

(b) obstruction above the larynx, such as retro-pharyngeal abscess ; (c) œdema of the glottis, due to sepsis, nephritis, urticaria, and various other conditions.

Prognosis. The mortality from diphtheria has been considerably reduced since the introduction of the treatment by antitoxic serum in 1893. In the hospitals of the Metropolitan Asylums Board during 1891, 1892, 1893, the annual mortality was 30 per cent. ; in 1913 to 1915 it averaged 7·17 per cent. The chance of recovery is diminished by every day, or half-day, that the treatment is delayed. Extensive formation of membrane, spread of the disease to the nose, rapid failure of strength, feeble pulse and hæmorrhages, are of unfavourable prognosis. Laryngeal diphtheria is more fatal, because, though laryngeal obstruction may be obviated by tracheotomy, death may occur from purulent bronchitis or broncho-pneumonia, caused by extension to the lungs. In these cases also the mortality has been much diminished by antitoxin. Diphtherial neuritis generally recovers, but is occasionally fatal through paralysis of the diaphragm.

Prevention. It must be remembered that the bacilli may remain in the throat long after the patient is himself quite well, and hence the risk of contagion remains. It is usual to keep a diphtheria patient from contact with others until bacilli can be no longer cultivated from the throat or nasal secretions. Sometimes a period of several weeks elapses before the patient is free ; but 50 per cent. lose them at the same time as the membrane, not more than 7 per cent. retain them for one month, and not more than 1 or 2 per cent. for three months (Ledingham and Arkwright). These carriers may be treated as described under Cerebro-spinal Fever. Favourable results have also been obtained with vaccines, but tonsillectomy may be required in the last resort.

Other measures of prevention are—taking care of the milk supply ; removal of susceptible children ; periodical swabbing of throats in institutions ; prophylactic injection of serum (1,000 units).

Undoubtedly the most important method of prevention is the Schick test (25). This test is used for determining whether individuals are susceptible to diphtheria infection or not. A small dose of diphtheria toxin—one-fiftieth of the minimum lethal dose for a 250-gramme guinea-pig in 0·2 c.c. of normal saline—is injected into the flexor surface of the forearm intradermally, not under the skin. The needle, which is of fine calibre, is passed nearly parallel to the skin within its substance. The injected fluid should appear and feel like a small button in the skin. A control injection of the toxin heated to 75° C. for ten minutes is made into the opposite arm. A “positive” reaction, which means that the individual is susceptible, is shown by a circumscribed area of redness accompanied by slight infiltration of the skin, measuring from 1 to 2 cm. in diameter. This appears in about twenty-four hours, and reaches a maximum in four or five days. There is no change on the control arm. In the “negative” reaction, which indicates immunity from diphtheria, there is no change in either arm. In a “pseudo” reaction, which indicates susceptibility to the foreign proteins of the injection and immunity to diphtheria, there is an equal area of redness in both arms, which is not so well defined, and reaches its maximum in twenty-four hours and rapidly fades. In the “combined” (positive) reaction both arms give a reaction ; but that of the inoculated arm is larger and usually presents a distinctly defined central red area. The “pseudo” element disappears early, leaving a persistent positive reaction.

By this test infants up to six months are found to be immune, and the percentage of persons susceptible to diphtheria is greatest between the ages of two and five years. This coincides with the age-period when the incidence of clinical diphtheria is greatest. Active immunisation with toxin-antitoxin has been carried out with success in susceptible people, and this may be of value in the case of doctors and nurses or of children when diphtheria is prevalent in the locality ; the tendency of public health authorities is to immunise all children up to six

or even ten years without preliminary Schick testing, because it has been found that most of them are positive (23).

Treatment. Immediately upon the diagnosis of diphtheria being known, and even before, if there is a high probability of the suspicion being confirmed by the bacteriological test, *diphtheria antitoxic serum* should be injected.

The initial dose required is from 10,000 to 40,000 units, according to the severity of the disease (*see Immunity*). If the case is urgent the serum (preferably the concentrated antitoxin-globulins) is injected intravenously or intramuscularly; otherwise it is made under the skin of the flank, or into the vastus externus, with antiseptic precautions. An effect is very often observed in a few hours either in the fall of the temperature or at least in the arrest of the progress of the symptoms. The dose may be repeated at intervals of twelve or twenty-four hours during the next two days, and the amount must be estimated by the intensity of the disease, and not by the age of the patient. Serum disease often follows these injections.

The general treatment described under Pyrexia should be employed. The fever is not often so high as to require special attention; but if the heart dilates, and the pulse becomes feeble, tincture of digitalis and other stimulants may be given. Recent experiments on animals suggest that blood transfusion may be of value in the circulatory failure associated with severe toxæmia (Harding).

The treatment of the throat in Faucial Diphtheria is the same as that described under Scarlatina.

For the removal of the offensive and irritating secretions when the nasal mucous membrane is involved the nostrils should be syringed with dilute disinfectant solutions, such as potassium permanganate and carbolic acid, or these may be administered by the nasal douche.

In laryngeal diphtheria the patient should be subjected to an atmosphere saturated with moisture. In a small room it will be sufficient to use a bronchitis kettle, the steam from which may fill the room. Much relief is also sometimes given by a hot bath. If improvement is not apparent in a few hours, intubation or tracheotomy should be performed, and this must be done at once if there is sucking in of the chest, if the patient is drowsy or becoming cyanosed, or if the forehead is cold and clammy. The probability of success is greater the earlier a tube is introduced into the larynx or trachea; and if it is suspected that the obstruction will increase, the operation should be done while the child is strong and of good colour. Generally in diphtheria tracheotomy is to be preferred to intubation. The latter is bloodless, and if it fails can be succeeded by tracheotomy; but it requires special skill in its performance, and the risk is run of pushing membrane down into the trachea. Nearly always some improvement follows an operation; the child breathes freely and deeply and sleeps tranquilly; but the danger of broncho-pneumonia still remains, and, as already mentioned, obstruction may take place from a plug of desiccated mucus lower down. To avoid this steam should be used, and oxygen, if given, should be passed through water. If obstruction occurs, spraying through the tracheotomy tube with sodium bicarbonate (10 grains to 1 ounce water) during inspiration may loosen the plug so that it is coughed up. In the last resort forceps should be passed down and the attempt made to get hold of the plug (Biernacki). Internally expectorants, such as ammonia or ipecacuanha in small doses, may be tried. The tracheotomy tube may often be removed in from one to four days. (See also Oxygen tent.)

If there are any signs of diphtheritic paralysis, the patient must be kept lying down. In the more severe cases, where swallowing becomes difficult, feeding by the nasal tube will be necessary. There will also be special danger in these cases of failure of the circulation. If the paralytic signs persist into convalescence, the patient should only be allowed to get up gradually, when all danger from the heart has disappeared. Strychnine in small doses is often prescribed for paralysis. Later on massage and electricity may be used for the muscles. They practically

always recover their function completely. In diaphragmatic paralysis the Drinker machine is used.

WHOOPING-COUGH

(*Pertussis*)

Whooping-cough is a disease characterised by a peculiar convulsive cough, followed by a long-drawn inspiration through the nearly closed glottis, by which a crowing noise, or "whoop," is produced.

It is spread by droplet infections, commonly from patients in the pre-catarrrhal stage; but healthy "carriers" of this disease have been known. Children are very susceptible, and most people have the disease in early life, while it quite rarely attacks adults. A second attack in the same patient is even more rare than in the case of the exanthems. It is most common between the ages of one and eight years, and girls are more liable to it than boys. It occurs in epidemics, but there is not much evidence that such epidemics are determined by climate or weather. It has often been observed that an epidemic of whooping-cough has immediately followed an epidemic of measles.

Pathology. Whooping-cough is caused by the bacillus of Bordet and Gengou (1907), which is now called the *Hæmophilus pertussis*. The blood serum of convalescent cases agglutinates this bacillus, and gives the deviation of complement reaction with it. Vaccines prepared from it have appeared to influence favourably the course of the disease (Freeman). While the cough must be due to the secretion set up by the organisms, the whoop is not so readily explained. It is generally thought to be caused by a spasmodic closure of the glottis, but a passive approximation of the cords, or a failure to open freely when the sudden inspiration takes place, would probably account for it.

The **Morbid Anatomy** of pertussis is that of its complications, usually broncho-pneumonia.

Symptoms. The period of *incubation* is seven to nineteen days. The limits are four to fourteen days. The first stage is catarrhal. There are cough, expectoration in children old enough, a few rhonchi in the chest, and slight pyrexia; but sometimes with the cough there is an unusual repetition of the expiratory effort, which may lead to suspicion of whooping-cough. This preliminary bronchitis lasts from seven to ten days, and then there is a more or less rapid transition into the second or convulsive or whooping stage. First, perhaps, a long-drawn inspiration follows the cough, and then an unmistakable "whoop." But the cough itself is as characteristic as the whoop. The child may be playing with its toys, apparently well, when it suddenly stops, seems distressed for a moment, and then perhaps runs to its mother or nurse. A short cough occurs; this is quickly followed by another and another without any intervening inspiration, each successive cough getting less loud and more stifled until they have mounted up to fifteen or twenty expulsive efforts in the course of seven or ten seconds. Then follows a long-drawn inspiration with loud laryngeal sound, the "whoop"; another burst of short coughs succeeds, with another "whoop"; and this sequence may occur once or twice more, with less violence and less noise, until finally a little tough mucus is expectorated, or vomiting takes place. During the coughing efforts the face becomes congested or cyanosed, the features swollen, the eyes starting from the head, the tongue hanging from the mouth, blood-stained saliva is coughed in all directions, and little relief takes place even from the inspiration, until the final expectoration of mucus or the cessation of the paroxysm. During this time the child is quite given up to the absolutely uncontrollable reflex process; a child in bed, when it feels the attack coming on, will seize the porringer and place it under its mouth, and in another few seconds it will be entirely at the mercy of the cough, and regardless of what is going on around. As a result of the obstruction to respiration during the coughing efforts,

hæmorrhages may take place, bleeding from the nose, mouth, or gums, subconjunctival ecchymosis, petechiæ under the skin, and in very rare cases cerebral hæmorrhage. Sub-lingual ulcer is characteristic. After a time the face often acquires a puffy and bloated appearance from the frequent obstructions to the return of blood to the chest. The attacks often appear to be spontaneous, but they constantly occur if the child cries or gets in a passion, or even if the child is disturbed, as when the nurse begins taking off the clothes for an examination of the chest. The number of paroxysms, which may, as above shown, include three or four actual "whoops," ranges from one to sixty in the twenty-four hours, but it is very rare to have more than forty attacks, and many cases never reach thirty in the twenty-four hours. In the intervals the child may be perfectly well, and is free from fever, unless there is some complication. The second stage of whooping-cough lasts a variable time, often from three to six weeks, but sometimes up to three months or more. The attacks gradually get less frequent, until they cease altogether, or as they diminish they may be accompanied by attacks of simple cough, not followed by a whoop, and this may last a few weeks longer. Death rarely occurs directly from the paroxysms; it may occasionally do so from prolonged closure of the glottis, or from cerebral hæmorrhage.

Other Complications and Sequelæ, however, occur which may make whooping-cough a serious and even dangerous complaint. Amongst the former may be classed *bronchitis*, which may continue throughout, and *broncho-pneumonia* (11·5 per cent. of 889 cases at the M.A.B. Hospitals in 1914). Often, but not always, the whoop is absent during broncho-pneumonia, as it is if any other febrile complication ensues. *Otitis* (6·5) is less frequent than in scarlatina and measles. General convulsions (2·7) sometimes occur, either as a direct result of the paroxysm or less commonly as the indication of cerebral hæmorrhage or thrombosis, or, it may be, of the onset of pneumonia. As sequelæ continued bronchitis, emphysema, and bronchiectasis with clubbing of the fingers occasionally occur. There does not seem to be any relation between whooping-cough and tuberculosis.

Diagnosis. This mainly depends upon the whoop, on the convulsive character of the cough, and on the regularity of the course from the catarrhal to the convulsive stage. Enlarged bronchial glands may cause a cough something like that of pertussis, but there will be no history of infection and no whoops; while other symptoms of independent lung diseases may be present. In whooping-cough the leucocytes are increased to 15,000 or 30,000 per cubic millimetre; and a differential count gives 60 per cent. of lymphocytes to 40 per cent. of polymorphonuclears, with a few eosinophils. These changes occur quite early, and are of use in diagnosis (H. T. Ashby). A certain diagnosis can be made from a culture of the *H. pertussis* by collecting the cough-droplets on suitable media in Petri dishes (9). It has been obtained from 75 per cent. of cases in the catarrhal stage, from 54 per cent. in the paroxysmal stage, and from only 9 or 10 per cent. after five weeks.

The **Prognosis** is to be made from the severity of the complications.

Treatment. The child should be kept in a warm but well-ventilated room, but confinement to bed is not necessary in an uncomplicated case. A variety of drugs has been used to check the paroxysms of pertussis. Belladonna is much used in the form of tincture, of which 2 or 3 minims may be given to a child two years old three times a day, and larger doses to older children. The dose may be cautiously increased up to 10 to 15 minims in a child of five or six. Dilute hydrocyanic acid (1 to 2 minims), chloral (2 to 5 grains), potassium bromide (2 to 5 grains), hydrobromic acid (3 to 10 minims), antipyrin (2 to 5 grains), and bromoform (2 to 5 drops mixed with almond oil and mucilage of tragacanth or acacia), have been given. Recently benzyl benzoate has been tried with great success. It is a powerful antispasmodic. A 20 per cent. alcoholic solution is used, and the dose is 5 to 40 minims in water three or four times a day, depend-

ing on the age and severity of the attack. Benzaldehyde may be added in amounts varying from 1 to 5 per cent., and this increases the effect. Treatment in the oxygen tent, with or without carbon dioxide, is very effective in stopping the paroxysms. Where the cough results from a tickling in the throat, relief may be obtained by painting the lingual tonsil with tincture of iodine. Broncho-pneumonia may also require treatment.

THE ENTERIC FEVERS

In the early part of the nineteenth century, the fevers, excluding the exanthemata, which were characterised by a definite cutaneous eruption, were divided into continuous and intermittent. The intermittent were those now known as malarial. When the continuous fevers were further differentiated they included typhus, typhoid, and relapsing fevers. Though the distinction between typhus and typhoid was convincingly demonstrated by Sir William Jenner in 1849 to 1851, the absence of characteristic features in individual cases led to difficulties, and until comparatively recently these two fevers were still in Germany included under the common name *typhus*, the former being called typhus exanthematicus, from the prominence of its eruption in typical cases, and the latter typhus abdominalis, from the presence of intestinal lesions with their corresponding symptoms. In English practice for many years the term *enteric fever* has also been in use both to represent this characteristic feature and to accentuate the difference from the pathologically distinct typhus. This distinction was confirmed when, in cases of typhoid or enteric, Eberth discovered a bacillus, now known as *B. typhosus*. In 1901, however, it was found that in some of these cases, which clinically could not be regarded as other than enteric, the causative bacillus differed in certain particulars from Eberth's organism. Two such organisms have been identified which have been called *B. paratyphosus A* and *B. paratyphosus B*; and it is found, as a rule, with certain exceptions to be mentioned hereafter, that the serum of patients suffering from typhoid fever will agglutinate only the *B. typhosus*, while the serum of a patient with paratyphoid fever, whether *A* or *B*, will agglutinate the paratyphoid bacillus, whether *A* or *B*, which is the cause of his illness.

At present, therefore, it is convenient to speak of all these forms as Enteric Fevers, or forms of enteric fever, and to distinguish them as

Typhoid Fever, due to the *B. typhosus*;

Paratyphoid Fever *A*, due to *B. paratyphosus A*;

Paratyphoid Fever *B*, due to *B. paratyphosus B*.

Typhoid fever will be first described, and subsequently the differences which are presented by the fevers caused by paratyphoid organisms.

TYPHOID FEVER

Typhoid fever is infectious chiefly through the excretions. It has a febrile period of about three weeks' duration, and occasionally one or more relapses of the same length. The distinctive pathological lesion is inflammation and ulceration of Peyer's patches in the small intestine.

The specific micro-organism discovered by Eberth is a bacillus, 2-3 μ in length, with round ends, and provided with from eight to twelve fine flagella of about twice its length. It bears a close resemblance to the *B. coli communis*, but can be distinguished from it by bacteriological tests. Eberth's bacillus has been found during life in the stools, in the blood, in the urine, in the sputum, and in the pus of abscesses resulting from periostitis and other similar lesions months and even years after the attack. After death it has been found in Peyer's patches, in the mesenteric glands, spleen (abundantly), liver, gall-bladder, kidneys, meninges, bone marrow, and, rarely, in the lungs and testicles.

Ætiology. Enteric fever shows little preference for either sex ; but age has a marked influence, and the disease is much more frequent amongst young people. The quinquennial period which presents the highest percentage of cases (viz. 27 per cent.) is that between fifteen and twenty years ; nearly 50 per cent. of the cases occur between fifteen and twenty-five, and more than 84 per cent. between five years and thirty (Corfield). The disease does, nevertheless, occur (1 or 2 per cent.) in people over sixty-five years of age. It is more prevalent in the latter part of the year—that is, in the four months August to November inclusive—and cases are more numerous during hot and dry weather than under the opposite condition. It is not affected by overcrowding, poverty, and uncleanness, in the same way as typhus and relapsing fever, which are transmitted by external parasites. As a rule, doctors, nurses, and students in hospitals do not take enteric fever directly from the patients. The agent of transmission is, in the vast majority of cases, the fæces ; and in those not very common instances in which nurses have contracted the disease from their patients it was probably by direct contact with linen or bedclothes soiled with the fæcal discharges. But bacilli are found in the urine in some cases, and are constantly present in the pus from the bone lesions (*e.g.* periostitis) which sometimes follow typhoid fever ; both these secretions may therefore be the means of transmitting the disease.

A frequent cause of the spread of typhoid fever in a town or a country district is the contamination of its water supply by the stools of a single case. The opportunity arises from the imperfect means so often employed for the disposal of sewage. In the country, wells used for drinking water may be poisoned in consequence of the soil being saturated with sewage which has leaked from a neighbouring privy or imperfectly constructed cesspool. In one case a well was contaminated by the slops from a laundress's house leaking into it ; enteric fever broke out in the house supplied by the well shortly after the laundress had received some linen soiled by the discharges from a patient with this disease. Where the drinking water is conveyed by pipes, the disease may find an entrance if the pipes by any chance are defective, and if they lie in a porous soil sufficiently close to any collection of sewage, imperfectly confined, which has received any enteric stools ; and a whole reservoir may be infected in the same way. Drinking water is, however, not the only source of danger. Epidemics of enteric fever have been traced to the milk supply, the probability being that the milk itself has been first infected by being stored in vessels washed with water exposed to contamination by typhoid sewage. Typhoid has also been traced to ice-creams sold in the street, and to oysters, cockles, mussels, and clams, supplied from breeding areas exposed to sewage contamination, and eaten uncooked. Water-cress or celery may be an agent in a similar way.

Contamination of food by flies, which have had access to the excreta of enteric patients, may spread infection. This fact was proved by experience in the Spanish-American war in 1898 and in the South African war.

But the transmission of the disease by the bacillus is not confined to the period during which the patient is suffering from the fever. Months or years after recovery, when apparently in perfect health, he may still be harbouring the bacillus ; and indeed the organisms may exist in those who are not known to have had typhoid fever at any time, and yet may be the cause of infection to persons coming into contact with them. These are all called *typhoid carriers*, and are divided into groups. *Convalescent* or *temporary carriers* are those who have had the disease within two or three months ; *chronic carriers* are those in whom the bacillus persists for months or years ; *healthy carriers* are those who are not known to have had the fever, and yet are infecting others ; and *early carriers* are certain persons, also healthy at the time when bacilli are found in their fæces, who only subsequently develop typhoid fever. The test of a carrier is that the bacilli should be found in the fæces or in the urine ; in a large proportion the blood gives the Widal reaction. That the bacillus of typhoid

fever is constantly found in the gall-bladder is well known, and in a large proportion of chronic carriers gall stones are formed and give rise to the usual difficulties. The carriers infect others by direct contact, or by unconsciously conveying the bacilli to water, milk, or things they handle.

Morbid Anatomy. The essential lesions of enteric fever occur in the *Peyer's patches* and *solitary follicles* of the small intestine. These become infiltrated with lymph corpuscles, and a Peyer's patch so affected swells, and projects upon the inner surface of the intestine; it is grey, fawn-coloured or pink, but the surrounding mucous membrane may have its natural colour. The lymph corpuscles at first multiply in the follicles, but subsequently infiltrate the mucous membrane above and the deeper structures below. As the patches become larger they acquire a creamy-white colour, and about the tenth day or a little later they begin to ulcerate or slough, presenting at first a superficial abrasion at one point of the surface, which becomes deeper and deeper until a great part of the gland is removed; or a whole patch may slough at once. When the slough is still adherent, it is often stained yellow by bile pigment. By these processes the muscular coat or the peritoneal covering may be exposed in the floor of the ulcer, and finally the peritoneum may slough, ulcerate, or tear, so that the contents of the bowel escape into the peritoneal cavity, and set up intense peritonitis. The stage of ulceration generally occupies part of the third week, and towards the end of that time, in favourable cases, the process of healing by cicatrization begins. Ulceration does not necessarily occur: in mild cases the inflammatory swelling subsides without any destructive change. The number of Peyer's patches affected is very variable, and though the cases with severe diarrhoea generally have extensive inflammation of the bowel, there is no necessary correspondence between the extent of ulceration and the severity of the other symptoms. The patches near the ileo-cæcal valve are those first attacked, and the process spreads upwards. The change in the solitary follicles of the lower end of the ileum is of the same kind, and in some cases the lymphoid follicles of the large intestine (mostly the cæcum) are also enlarged and ulcerated. Coincidentally with these lymphatic structures of the intestines the *mesenteric glands* are inflamed; they are enlarged, fleshy, pink, red, or purplish, and their histological changes resemble those of Peyer's patches. The other post-mortem appearances are similar to those that occur in any febrile condition (*see p. 18*).

Symptoms and Course. The period of *incubation* is three to twenty-three days, usually about a fortnight. The beginning of the disease is often very little marked. The patient feels ill, depressed, unfit for work; he has headache, pains in the limbs and back, loss of appetite, and perhaps nausea. These may come upon him so that he scarcely knows when they began, but he can frequently fix a day on which he says he first fell ill. Often the headache is severe, and forms the most prominent complaint. There may be diarrhoea in the first few days. Constipation, however, is also extremely common. Sometimes on the first feeling of illness a purgative is taken, and the bowels continue loose. The patient may go about, struggling to do his work, for five or six days, but generally towards the end of the week he is obliged to give up and take to his bed. The temperature has been stated, in the first four or five days of enteric fever, to rise two degrees each evening, and to fall one degree each morning, so that at the end of that period it will have reached 103° or 104°. So many cases escape accurate observation in the early days that it is not always easy to confirm this, but it is certain that in some cases the thermometer may rise on the first evening of illness to 103° or higher. The high level of 103° to 104° once reached, the temperature commonly remains at nearly the same level till the tenth to the fourteenth day, oscillating, however, between morning temperatures of 102° to 103° and evening temperatures of 103° to 104·5°. The pulse is quick, full, soft, and markedly dicrotic. Though in some cases very rapid, it is generally, in relation to the temperature, much slower than in typhus and many other

febrile conditions ; it may never exceed 100, and a pulse of eighty may co-exist with a temperature of 102° or 103°. The respirations are increased in frequency, and there is very frequently slight bronchitis, indicated by sibilant rhonchi, and accompanied, it may be, by mucous expectoration. About the seventh to the tenth day the patient commonly begins to present the characteristic appearance of enteric fever. He is dull, listless, apathetic, but not so dull and stupid as in typhus ; the eyes brighter, the pupils often dilated ; the face pale, with flushed cheeks and dark lips ; the tongue dry, with a band of dry white fur on each side, the sides, tip, and middle clean and red. As the disease progresses, or in severe cases, the tongue tends to become thickly furred and dry all over its surface. Occasionally profuse perspiration occurs, or bleeding from the nose. At the end of the first week, or later—that is, from the sixth to the twelfth day—appears the characteristic *rose rash* of enteric fever ; it consists of rose-pink spots, circular, slightly raised above the surface, flat, convex, but not pointed, so that they are often described as *lenticular*, from 2 to 4 mm. in diameter, disappearing under firm pressure with the finger, and never petechial like the typhus rash. They are seen first on the abdomen and front of the chest, and may be confined to these parts ; but they also occur on the sides, back, and the upper arms and thighs. In number they vary from half a dozen to twenty or thirty, but they may be much more numerous, and in a certain number of cases (10 to 20 per cent.) are entirely absent. Each spot has a limited duration, gradually fading in three or four days ; but spots continue to come out day after day until the end of the third week, or in some cases even later. They are not visible after death. In the second week also the *intestinal symptoms* become prominent. The abdomen is generally full, even distended, and resonant on percussion ; and there may be both tenderness and pain, but the former is more common than the latter. Pressure in the right iliac fossa, over the seat of the cæcum and lower end of the ileum, often elicits a little pain. *Diarrhœa* is a familiar symptom of enteric fever, but it is very variable in duration and in severity. Often there is a sharp attack of diarrhœa in the first week, and after this the bowels are confined ; sometimes (up to 40 or 50 per cent. of the cases in some epidemics) there is *constipation* throughout. In other cases diarrhœa is constant, and the motions number three, four, or five or more daily. The stools, moreover, are distinctive in being liquid, of the colour of pea-soup, and of a peculiar offensive odour. They commonly contain particles of undigested food, intestinal epithelium, bile pigment, micrococci and bacilli, crystals of ammonium-magnesium phosphate, and after a time shreds of sloughs from the diseased Peyer's patches. They are alkaline and ammoniacal. The intestinal lesions further show themselves occasionally by the occurrence of *hæmorrhage*. This often happens in the stage of separation of the sloughs or of ulceration, and large quantities of bright red blood are discharged from the bowel, so as to cause severe collapse, with pallor and depression of temperature ; but the bleeding may be quite slight, and this more often in the earlier stages of the illness. The *spleen* is generally enlarged ; this may be manifest only from the results of percussion ; but in most cases the organ can be felt on deep inspiration 1 or 2 inches below the costal margin. The *urine* is scanty, dark, and of high specific gravity ; the urea and uric acid are increased, but the sodium chloride is much diminished. Late in the illness albumin is found in a small proportion of cases. But for the headache and some giddiness the cerebral functions may be very little disturbed in mild cases ; the headache rarely lasts beyond the tenth day, and there may be then only a little drowsiness or tendency to wander at night. A temporary deafness is not uncommonly noticed. Such mild cases reach their acme at the end of the second week—the tenth to the fourteenth day. The temperature then takes a characteristic course ; hitherto standing always at a high level, it now falls every morning quickly lower and lower, while the evening temperatures, though also falling, come down much less rapidly. Thus the morning temperature in four or five

days reaches 99° or 98° , while the evening temperature stands at 102° or 101° . This may be called the *remittent* stage. From this point to the end of the illness the fever has for three or four days an *intermittent* character; it is about normal in the morning, but rises to 101° or more in the evening. Then rather suddenly the evening fever ceases, the temperature remains normal or subnormal, and convalescence has commenced. During this falling temperature spots may continue to come out, the spleen is still perceptible, and there may be a little diarrhœa; but the mental condition of the patient generally improves, and he often acquires an appetite some days before the fever has entirely left him.

On the other hand, the graver cases are mostly accompanied by an increase in the intensity of the nervous symptoms, to which the symptoms of cardiac failure, or severe abdominal troubles, may be added; more or less continuous delirium may supervene, with drowsiness or even coma, extreme muscular prostration, subsultus tendinum, and plucking at the bedclothes. The face

FIG. 6.—Temperature in a Case of Enteric Fever with Relapse.

becomes dusky, the tongue dry, sordes collect on the lips and teeth, the pulse is rapid and soft, the heart sounds are feeble, and the bases of the lungs are congested, as shown by râles and a very feeble respiratory murmur. The urine may be retained, or both fæces and urine are passed unconsciously. The condition resembles that described under Typhus Fever; the patient is in a truly *typhoid* state. The delirium is less often violent than in typhus, but occasionally patients get out of bed or refuse food. Sometimes there is evidence of cardiac dilatation, and the pulse may be irregular or intermittent. With the increase of the nervous symptoms the abdominal troubles are often prominent, the diarrhœa becomes profuse, and the abdomen is much distended, tense and tender; in this stage the ulcerated bowel may give way, and peritonitis may result from the escape of fæcal matter into the cavity of the abdomen. Death may occur almost at any time after the tenth or twelfth day; but recovery occurs after lengthened periods of coma and other severe symptoms, the temperature slowly returning to the normal, and convalescence being very protracted.

Relapses. A true relapse of enteric fever occurs in a certain proportion of cases, which have been found by different observers to be from 3 to 10 or 11 per

cent.¹ It consists of a repetition of all the phenomena of the illness: ulceration of Peyer's patches, fever, diarrhoea, and rose spots; and it occurs after an interval which may be as long as eleven days from the termination of the original fever, but is often much less. Sometimes, indeed, there is no interval of actual apyrexia, and the relapse seems to be continuous with the primary fever. Its duration is often quite as long as that of the first attack (Fig. 6), and, as a rule, it is somewhat milder. Death may, indeed, take place in the relapse, but this is more often from complications, such as perforation of the intestine and peritonitis, or hæmorrhage, than from the severity of the pyrexia or toxæmia alone. Occasionally a second relapse occurs after another interval of apyrexia; and even third and fourth relapses have been observed, though very rarely.

Complications. The complications are numerous and varied, but a large proportion of patients escape them. As might be expected, the most important are those connected with the intestinal lesions.² *Hæmorrhage* (6·0) has been already mentioned (see p. 74). *Peritonitis* is a frequent cause of death. It arises most commonly from perforation of the floor of one of the ulcerated Peyer's patches, through which the contents of the bowel are extravasated into the peritoneal cavity; it occasionally happens from extension of inflammation through the peritoneal coat without any perforation being discovered; and it has also been caused in rare cases by the softening of inflamed mesenteric glands and infarctions in the spleen, and by rupture of the gall-bladder. *Perforation* of the bowel takes place in more than 30 per cent. of fatal cases of typhoid fever. In more than two-thirds of the cases it occurs in the second, third, or fourth week, but it is rare before the ninth day. The perforation usually occurs in the last 2 feet of the ileum, and not infrequently there may be two or more perforations. Its onset is often accompanied by acute pain, collapse, and perhaps vomiting or rigors; the abdomen is tender, sometimes flat and rigid, at others distended, but in both cases moving scarcely at all on respiration; the pulse is small and rapid, and the temperature sometimes falls. But its advent may only be marked by collapse and increased distension; and in very severe cases, with much distension of the bowel as well as coma and delirium, there may be no certain signs to indicate peritonitis, so that perforation and peritonitis are occasionally found post mortem when not suspected during life. A progressive increase in the total leucocyte count from hour to hour is a valuable diagnostic point in doubtful cases. So long as the ulcer remains unhealed there is a possibility of a rupture taking place; and such a rupture may be induced by any disturbance of the bowel, as by vomiting, defæcation, the exertion of sitting up, or the administration internally of indigestible food or of aperients; and thus even cases which are running a mild course may be fatal from this cause. *Ulcerations of the pharynx* have been observed. They are mostly superficial, situate upon the pillars of the fauces, and sometimes accompanied by swelling of the lymphatic glands; they may occur early in the illness, and have been wrongly attributed to syphilis or diphtheria.

A slight amount of *bronchitis* is frequent in enteric fever, but occasionally it is so severe as to constitute the main feature. The face may be quite livid, and a more or less venous tinge may be given to the whole surface; the chest is filled with râles and rhonchi, and there is expectoration of mucus or muco-pus. *Ulceration of the larynx* occurs sometimes in severe cases. The ulcer is situate commonly over the arytenoid cartilage, and this may be even exposed and in a state of necrosis. Sometimes an abscess forms around the cartilage in consequence of *perichondritis*. As results of these laryngeal com-

¹ At the Metropolitan Asylums Board's hospitals in twelve years from 1900 to 1911 the percentage was 10·3. In 1914 in 316 cases the percentage of relapses was 6·96.

² The bracketed figures in italics represent the percentage occurrence of each complication among 316 cases in the Metropolitan Asylums Board's hospitals in 1914; no later data have been published.

plications there may be hoarseness or complete aphonia ; subcutaneous emphysema, from air being forced during expiratory efforts from the larynx into the connective tissues ; and cicatricial stricture of the glottis in cases that recover. A temporary aphonia may occur without any evidence of ulceration. *Pneumonia* sometimes becoming gangrenous, *broncho-pneumonia* (5·4) and *pleurisy* (0·9), both serous and purulent, occasionally occur, and much more rarely *pneumothorax*. *Jaundice* is of rather rare occurrence ; it may be due to hepatitis or to the well-established affinity of the bacillus for the gall bladder. The stools are not necessarily deprived of bile pigment, and recovery may take place without any further indications. There may be *cholecystitis*. *Acute nephritis* (1·3), sometimes with abundant albuminuria or hæmaturia, may occur. In about one-fourth of the cases of enteric fever the bacilli are found in the urine, especially in the third week ; sometimes they are so abundant as to cause a visible deposit (*bacilluria*), and sometimes they give rise to *pyelitis* or *cystitis*. They may persist there for years, as has been stated in connection with typhoid-carriers. *Otitis* (3·2) and *otorrhæa* may occur during or after the fever, and may lead to deafness, or to the more serious conditions of *septicæmia* and *meningitis*. Meningitis from the typhoid bacillus has been recorded as occurring without intestinal lesions. Double *optic neuritis* is sometimes seen, but it is rare. Other local inflammations occasionally occur either during the fever or during convalescence, and may considerably delay recovery, such as *parotitis* (0·3), which may be followed by suppuration, or extensive infiltration of the neck ; *orchitis* ; *myositis* ; *cancrum oris* ; abscesses (2·2), boils (0·6) and facial *erysipelas*. *Periostitis* (1·3) occurs especially on the tibiæ, but also in other bones, such as the ulna or metacarpals ; and *perichondritis* of the costal cartilages may occur. Pain in the lumbo-sacral region aggravated by walking, and persisting for a long time, has been called *typhoid spine* ; in some cases the Röntgen rays have shown ostitis, periostitis and perichondritis about the lumbar or lower dorsal vertebræ. Another condition is described as *tender toes* ; in this the toes and soles of the feet are painful on pressure during attempts at walking. In severe cases *bed-sores* may form, in spite of careful nursing. *Thrombosis* (2·2) of the femoral vein, generally on the left side, may occur during early convalescence, leading to œdema of the foot and leg, and tenderness in the course of the vein. It mostly subsides without much trouble, but the thrombosis may extend into the large abdominal veins, or portions of clot may be detached, and lead to pulmonary embolism and death. *Rigors* are of rare occurrence. Among the nervous sequelæ, besides meningitis, are *encephalitis* (rarely) ; *mental disturbances*, especially a Korsakow's syndrome, and in a few cases a permanent memory defect ; *peripheral neuritis* and, rarely, localised muscular atrophy.

Varieties of Typhoid Fever. There are few diseases more variable than typhoid fever. Though its duration is characteristically three weeks, it may be as short as ten days or as long as five or six weeks ; and though short attacks may sometimes be fairly represented as abortive attacks, they may be followed by a relapse of precisely the same nature and duration. Sometimes the temperature begins to fall in the manner described (see p. 73), and then, before reaching the normal, persists in its remittent type, oscillating between 100° (morning) and 102° (evening) for eight or ten days, so that the fever is prolonged into the fifth week, although the patient is feeling better every day, and has no obvious complications. In other cases the prolongation of the fever corresponds with a continuance of the high temperature characteristic of the second week, and these are generally severe cases. In some cases the illness is so slight that patients go about their ordinary occupations until, perhaps, an indiscretion in diet or the use of aperients, given in ignorance, leads to a fatal perforation. Cases so mild as this in their general symptoms, and yet so dangerous from their possible termination, have been called *ambulatory typhoid*. Ataxic and adynamic forms have been described, but these terms simply indicate the predominance of

symptoms in one or other system of the body. Very rarely a *hæmorrhagic* form occurs, in which there are purpuric eruptions on the skin, bleeding from the mucous membranes, epistaxis, hæmoptysis, hæmatemesis, and hæmorrhage into the muscles and internal organs. (Compare Measles and Small-pox.) Typhoid fever is very often mild in children, often of short duration, and associated with less extensive disease of Peyer's patches than in the average of adult cases. The remissions of temperature, which are well marked in the latter half of the illness in adults, are often still more marked in children, and the "infantile remittent fever" of older writers was undoubtedly enteric fever. In elderly persons also the rose spots and enlarged spleen are often absent.

Diagnosis. In every case of pyrexia which is in any way suggestive of enteric fever, an attempt should be made at the earliest possible moment to isolate the organism by blood culture. Blood is withdrawn from a vein under strictly aseptic precautions; enough sterile sodium citrate is added to make a 0.5 per cent. solution. This is to prevent clotting. The blood is then mixed with 5 to 10 times its volume of sterile broth and incubated at 37° C. At least 5 c.c. of blood should be withdrawn and several culture tubes prepared. Blood culture gives a high proportion of positive results if performed within the first seven days of the disease. It may, however, be positive very much longer, and, at whatever stage of the disease the patient is seen, it should always be attempted. In cases of over seven days' duration a specimen of blood should also be taken in order to test the agglutinating power of the serum against the enteric group of micro-organisms (Widal's reaction). It is advisable as a routine measure to send specimens of fæces and urine for cultivation. Positive results, however, cannot be secured at all stages of the illness, and negative reactions must not be hastily regarded as excluding the disease. It is therefore necessary to give full consideration to all the clinical features of the illness, as well as to the several points in the ætiology and history of the case. The Widal reaction is not usually positive until about the fourteenth day of the disease, but may remain so for many months after convalescence. The value of the reaction in the diagnosis of the paratyphoid fevers and in persons who have been inoculated is discussed later.

A great number of diseases may be confounded with enteric fever, from the variety of forms which it assumes, and from the frequency with which its own typical symptoms are absent or badly marked; but it may be briefly stated that the characters which are the most constant and the most suggestive of the enteric fevers are *headache*, *persistent fever*, *rose spots*, and *enlarged spleen*.

In early stages it is distinguished from the exanthems by the absence of characteristic eruption. Severe joint pains may lead to a suspicion of rheumatic fever. A prolonged febrile complaint which has come on insidiously, and presents no obvious local lesions, should always make one think of enteric fever; but the great prevalence of *influenza* gives rise to frequent mistakes. For though influenza is often a much more sudden and quickly prostrating disease, it presents so much variety that almost any illness beginning with headache, backache, and fever is liable to be mistaken for it. If typhoid fever is present, the temperature remains high, or even rises, and the diagnosis may be soon confirmed by diarrhœa, enlargement of the spleen, or rose spots. Tenderness over the gall-bladder and muscular resistance in the right hypochondrium are said to be early signs of typhoid infection, but of course they may be due to local inflammatory lesions.

Later stages present a resemblance to different diseases according as the head, chest, or abdomen shows the most prominent disturbance. Thus the headache of typhoid, which rarely continues beyond the tenth day, and the subsequent delirium may suggest *tuberculous meningitis*, and the two diseases are frequently confounded together. Lumbar puncture and the examination of the cerebro-spinal fluid for cells and protein and tubercle bacilli will decide the diagnosis. When pulmonary symptoms are marked, *acute general tuberculosis* may be simu-

lated by the abundant bronchitic râles and crepitations accompanied by a remitting fever. The abdominal diseases which may be confounded with typhoid fever are especially *tuberculous peritonitis* and *appendicitis*. In both there may be high fever, abdominal distension and tenderness; and in tuberculous peritonitis the stools may be frequent and yellow from accompanying tuberculous ulceration. In appendicitis there is localised pain and tenderness. The *pyæmic* or *septicæmic* condition associated with abscess or suppuration in other parts of the abdomen, such as hepatic abscess and perinephritis, may also give rise to confusion; and the rare disease *suppurative pylephlebitis*, in which local evidence of the liver being involved may be little or none, must not be forgotten. In most of these conditions *leucocytosis* is present. *Infective* or *malignant endocarditis* is not infrequently mistaken for typhoid fever. Trichinosis, the disease caused by the multiplications of the *Trichina spiralis* within the body, has been mistaken for typhoid fever; it is distinguished by severe muscular pains, œdema of the eyelids, and sometimes of the whole body.

Undulant fever presents some resemblances to typhoid fever, and should be thought of when the illness has been contracted in places where the former disease is prevalent. Certain types of malarial infection, especially malignant tertian, may almost exactly simulate typhoid fever. They may be distinguished by the demonstration of parasites in the blood, the evidence of red cell destruction seen in a blood-film and the reaction of the pyrexia to quinine. It must not, however, be forgotten that malarial infection and typhoid fever not infrequently co-exist in the same patient.

An examination of the blood (*see Diseases of the Blood*) may give some help in diagnosis. In all but the earliest stages of typhoid fever there is a reduction of the neutrophil leucocytes, which reach their minimum in the period of declining pyrexia. The lymphocytes are also diminished at first, but increase again at the end of the stage of continuous pyrexia, and remain abundant throughout the fever, and for some weeks into convalescence. Eosinophils disappear at first, and reappear with the increase of the lymphocytes (Nägeli). Secondary infections, or other complications, may increase the leucocytes again, especially the polymorphonuclear cells.

Marris has found that in the enteric group of fevers the heart's action is not quickened by atropine to the same extent as it is in healthy persons. This difference is observed about the tenth day of the fever, though sometimes earlier; and the normal response to atropine may be resumed at any time after the fourteenth day, though it may persist much longer, and will vary with relapses. In persons over fifty years of age, and in those suffering from heart disease or from arterio-sclerosis, the failure to quicken may be due to pre-existing cardio-vascular changes, and not to the typhoid poison.

The pulse rate is taken and recorded minute by minute till it is steady. One thirty-third of a grain of atropine sulphate is then injected subcutaneously, best over the triceps. After twenty-five minutes the pulse is again recorded minute by minute till it is clear that its rate has reached its highest point, and is now falling. Marris concludes that an increase of the pulse rate by twenty or more beats in the minute after atropine may be accepted as an indication that the patient is probably not suffering from typhoid fever or one of the paratyphoid series. An increase of less than ten beats is suggestive of infection by one of these diseases. Readings between ten and twenty are uncertain.

Prognosis. The mortality of typhoid fever varies in different epidemics from 5 to 20 per cent. Complications contribute largely to the deaths, and their occurrence will modify the prognosis at any time. Apart from them, the intensity of the fever is an important guide. If the temperature is, although high at the end of the first week, subsequently never above 103°, the case is favourable; if the temperature is maintained at 104° or higher throughout the second week, it is much more dangerous. Some cases sink rapidly by the twelfth, eleventh, and

tenth days, or even before this. Perforation is almost certainly fatal unless it is promptly treated by surgical methods. Hæmorrhage is less dangerous, but may be responsible for about one-fifth of the deaths; and the mortality amongst cases with free hæmorrhage is much above the average. A severe hæmorrhage, even if not fatal, renders the patient very anæmic, and considerably prolongs convalescence. Much abdominal distension, profuse diarrhœa, incontinence of urine and fæces, severe general bronchitis, and a feeble and irregular heart, are all unfavourable.

Prevention. Since typhoid fever is spread mainly by the fæcal discharges and the urine, these should be disinfected as described in the introduction. Soiled bed-linen, clothes and towels must also be disinfected. Specially marked crockery should be put aside for the patient's meals and a bowl of 2 per cent. lysol is placed by the bedside, so that the hands of doctors and nurses can be sterilised after attending the patient.

Preventive Inoculation. But even if the risk of exposure to infection cannot be avoided it is possible to diminish the susceptibility of the individual by the inoculation of a vaccine consisting of dead cultures of typhoid bacilli. This has been done as a routine measure in the army for some years. A vaccine containing 500 millions of bacilli is first injected, and a second injection of 1,000 millions is made ten days later. A certain amount of local and general reaction takes place, but soon subsides. It is estimated that the liability to the disease was thereby reduced to one-eighth, and the mortality among those who had the disease to one-half; but still more striking figures have been published. Moreover, both larger and more frequent doses have been inoculated. An inoculation of 1,000 millions should be repeated at about yearly intervals.

The treatment of typhoid-carriers presents many difficulties. Intestinal antiseptics are valueless; and the gall-bladder has been drained, and even removed, in some cases with notable success. The use of vaccines has been tried in doses of several millions of sterilised typhoid bacilli at intervals of two or three weeks; but even if the organisms disappear for some time from the urine and fæces the permanence of the cure cannot be guaranteed. The only efficient means of meeting the difficulty of the typhoid-carrier is to keep him under observation and ensure disinfection of his excreta until he is shown to be permanently free. Particular care must be taken that his employment does not in any way necessitate his handling or preparing food for other persons. In purely urinary cases urotropine will reduce the number of bacilli as long as it is being taken.

Treatment. The general treatment of pyrexia applies to a case of typhoid fever, and the description already given should be consulted. The special dangers of perforation and hæmorrhage from the ulcerated bowel should never be lost sight of. In choosing a diet special care must be taken to avoid articles of food that leave a residue or may irritate the ulcers and cause perforation. Not so long ago milk alone was allowed, but at present a varied diet of 2,000 calories or more is prescribed which may include thin bread and butter without crust, mashed potatoes, vegetable juices and fruit juices (*see* Pyrexia).

As to medicinal treatment, in mild cases little or none is wanted. A small dose of dilute mineral acid, or of a saline diaphoretic like the acetate of ammonium, may be grateful to the patient; and the body may frequently be sponged with tepid water. Stimulants are often unnecessary. If required, they may be given on the principles laid down (*see* Pyrexia).

This purely expectant line of treatment suffices in many cases, especially those of milder type; the patient is cared for while the disease runs its course. The methods of treatment by which it has been sought to influence directly the progress and prevent the accidents of the fever are those by (1) hydrotherapy, which has done much to lower the mortality in typhoid (*see* Treatment of Pyrexia), (2) antiseptics, and (3) antitoxic serum or vaccine.

The *antiseptic* treatment consists in the use, internally or by enema, of such drugs as carbolic acid, sulphurous acid, naphthol, hydronaphthol, naphthalene, bismuth salicylate, salol, oil of cinnamon and chlorine. They are said to diminish diarrhoea and tympanites, and to make the stools less offensive; but they have little or no influence on the changes in the bowel, or on the duration of the pyrexia, nor do they prevent relapse. The doses employed for adults have been of β -naphthol 3 to 5 grains, suspended in mucilage, every four hours, of hydronaphthol 2 to 3 grains every two to four hours, of sulphurous acid 20 to 30 minims, of salol 5 to 7 grains, and of oil of cinnamon 3 to 5 minims every two hours.

The treatment of enteric fever by a *serum* is yet in its infancy. The recognition that the poison of the typhoid bacillus was mainly an endotoxin, and that little exotoxin was formed, suggested that the bacterial cell juices should be injected into the horse in order to produce an *anti-endotoxic* serum. Such a serum, employed in the treatment of typhoid fever, has awakened hopes that it may influence the course of the disease (Macfadyen, Hewlett).

Non-specific protein therapy in the form of T.A.B. vaccine, given in a dosage of 150 to 250 million organisms intravenously each day for four to six days has been very favourably reported on. Severe rigors follow the injection. Not infrequently the fever is terminated by crisis, and in other cases there is marked amelioration or complete abolition of the toxæmic features. Hyperpyrexia is best avoided by not giving the injection at a time when the temperature is actually rising. Rarely cardio-vascular shock and hæmorrhage have followed the injection.

Special symptoms of complications may have to be met, such as bronchitis, by small doses of expectorants (*see also* Bronchitis), or persistent headache by phenacetin, 5 to 10 grains, or aspirin, 5 to 10 grains. If the bowels are not opened more than four times in the twenty-four hours, no treatment is required; but it is generally desirable to check diarrhoea if it exceeds this limit, and this is best done by the use of a starch enema with 15 to 20 minims of tincture of opium; and bismuth carbonate or salicylate, or the vegetable astringents, may be given internally. Any linen that is soiled by fæces or urine should be at once removed, not only for the sake of keeping the patient clean and free from the risk of bed-sores, but also to prevent the possibility of the attendants being infected. If constipation occurs, the bowels may be left for two or three days without harm, and it is then safest to use a soap enema from time to time as required. In cases where meteorism is marked, this symptom may be relieved by injection of 1 c.c. of pituitary extract.

For hæmorrhage from the bowels opium internally or morphia by hypodermic injection is probably the best treatment. Acetate of lead, tannic acid, oil of turpentine (10 minims), ergot, and adrenalin chloride have at different times been used, and more recently chloride of calcium in 10-grain doses every three or four hours, or intramuscular injections of calcium chloride, gr. i. to 100 minims of distilled water. Tympanites may be relieved by the application of ice, in small lumps, between two pieces of flannel, and by use of turpentine enemas.

If perforation is recognised, laparotomy should be performed at once, the abdomen should be washed out, and the ulcer closed. Without operation the condition is practically invariably fatal. With operation the recovery rate is about 20 per cent. It has been shown that the prognosis is very much better if laparotomy is performed within twelve hours of perforation occurring.

Both for the treatment of bacilluria and cystitis when they occur, and for the prevention of infection in others, urotropine (10 grains three times a day) or helmitol should be used during the fever and for three weeks of convalescence.

During convalescence purgatives must be carefully avoided, or used only in the form of enema. Even in favourable cases without complications or sequelæ the bodily and mental vigour returns with remarkable slowness, and the patient

should not be too early allowed to exert himself. Rarely is he fit for work under three months from the commencement of the illness, and in the graver forms, or in case of relapse or of complications, this period may be prolonged to five or six months. Specimens of fæces should be examined bacteriologically on three separate occasions during convalescence in order that typhoid-carriers may be detected.

PARATYPHOID FEVERS

The organisms which cause paratyphoid fever are two in number, distinguished as *Bacillus paratyphosus A* and *B. paratyphosus B*. They differ from *B. typhosus* in cultural characters such as their fermenting action on different sugars, their action on milk, and their agglutinative reactions.

These two have had a somewhat different geographical distribution, the *B. paratyphosus A* having been found in many parts of the world, including Germany and India, but rarely in England, whereas the *B. paratyphosus B* was found more commonly in England, but also in Germany and America. But both forms have been present in the enteric fevers prevalent in the Dardanelles and in Egypt during the Great War, and there the cases of paratyphoid outnumbered those due to *B. typhosus*.

Ætiology. The ætiological factors in the spread of the paratyphoid fevers appear to be the same as those which favour typhoid itself. The diseases are spread chiefly through the fæces of those who are ill, and of the different groups of carriers, but also by clothing, bedclothes, etc. Drinking-water, milk, flies, dust, shellfish and other agents are concerned in different cases as in typhoid.

Symptoms and Course. The symptoms and pathology of the two forms are identical, and they can only be distinguished from one another by agglutination tests or by isolation of the bacillus from the blood or fæces. They are also not materially different from the symptoms and the pathology of typhoid itself, and the following are the chief conditions which have been observed to be more or less frequent than in typhoid. Thus it is stated that a sudden onset is more common in the paratyphoids; that the rose spots are redder and more profuse; that the spleen is more often or more considerably enlarged; that the pulse is unusually slow, as compared with the elevation of temperature, so slow even as fifty in the minute; that abdominal pain is not infrequent, and hence a risk of confusion with appendicitis, and if there is much diarrhœa with dysentery; but the great variations in the symptoms of typhoid fever must not be forgotten.

The duration of the pyrexia may be as little as ten days, but it may be as much as eighteen or twenty-one days, the longer period more often in paratyphoid A than in paratyphoid B. It oscillates often between 100° and 102°, and is rarely above 103°.

The spots are as variable in number as in typhoid, and in the shorter forms may not appear till near the end of the pyrexia.

In the paratyphoid fevers complications occur similar to those seen in typhoid fever; that is, there are inflammatory lesions of other organs besides the intestine, due either to the paratyphoid bacillus or to other infections. And sometimes these occur so early in the disorder as to distract attention from the main disease unless the specific tests are applied. By Dr. C. H. Miller several forms of paratyphoid fever are recognised, determined by the organs or systems most severely or earliest attacked in different cases. Thus he describes dysenteric, biliary, nephritic or urinary, pulmonary, rheumatic, influenzal and septicæmic varieties. Accordingly during paratyphoid epidemics the possibility of this infection must always be remembered in cases of jaundice, dysenteric diarrhœa, acute bronchitis, pneumonia, or nephritis.

The mortality among paratyphoid cases has generally been regarded as slight, namely, from 1 to 3 per cent.; but in cases occurring among soldiers it has sometimes been as high as 5 or 6 per cent. (Miller).

Post mortem in some cases no intestinal lesions have been found, in others ulceration of Peyer's patches, or of the solitary follicles in the ileum, cæcum and colon. Enlargement of the spleen and of the mesenteric glands is also found.

Diagnosis. The diagnosis between paratyphoids A and B and typhoid infection can only be made with any certainty by bacteriological examination and agglutination reactions. A positive finding from culture of the blood, urine, or fæces will decide the diagnosis at once. Failing this, the serum of the patient must be tested for agglutinating power against the various organisms. If the patient has never received any prophylactic inoculations against the enteric group of organisms, diagnostic results may be obtained by an agglutination test on one occasion only. If, however, he has at any time been inoculated with typhoid organisms or with a mixed vaccine of typhoid and the paratyphoids, the agglutination reactions are markedly affected. In such cases, to be of any diagnostic value, the tests must be performed by the quantitative macroscopic method introduced by Dreyer. He has shown that there is a gradual rise followed by a fall in the agglutinating power of the serum towards the organism that is causing the infection. In order to establish this agglutination curve at least three tests must be carried out at intervals of about four days. Thus, for example, in a case of paratyphoid A who has been inoculated with all three organisms it will be found that the serum agglutinates all three, but that there is a rise of agglutinating power for paratyphoid A, followed later by a fall as convalescence is established.

Prevention. The known ætiological factors, drinking-water, soiled clothes, flies, dust, etc., have all to be considered; and preventive inoculation by means of vaccines prepared from the two kinds of bacilli can be employed where, as in the case of a campaign, the risk of infection is almost certain to be incurred.

Treatment. This is the same as is required in typhoid fever.

TUBERCULOSIS

Tuberculosis is an infection by a specific micro-organism—the *Bacillus tuberculosis* of Koch, which is characterised by the formation in one or more organs of certain bodies called *tubercles*.

Ætiology. Tubercle bacilli are minute rods, straight, or very slightly curved, measuring 3μ in length and 0.5μ in breadth (see Diagnosis of Phthisis). Certain observations point to the possibility that tubercle bacilli are not, as formerly thought, fission fungi, but that they belong to the class of *Streptothrix*, one of the Hyphomycetæ. The bacilli are widely spread in nature. Human, bovine, avian, reptilian and piscine types exist, having different biological characters. It is claimed that by special methods of cultivation these differences can be abolished. Both human and bovine types are pathogenic to man.

Tuberculosis is practically an endemic disease: the human type of bacillus is probably widespread in all large communities; and there is good reason to believe that it infects and causes the growth of tubercle in a great number of persons, without its presence ever being detected. Post-mortem observations show that old healed foci of tuberculosis are present in most people. Living bacilli have also been found latent in the glands of about 10 per cent. of people where the autopsy has revealed no macroscopic or microscopic evidence of tuberculosis. The conditions determining its development are (1) the virulence of the organism, (2) the susceptibility or resistance of the recipient individual, and (3) the mode of introduction.

1. Under the first head there is little that can be said but that the *virulence* undoubtedly varies.

2. In regard to the *condition of the recipient* importance attaches to *hereditary* influence. The conclusion has been drawn from statistics that the children of tuberculous individuals have a special hereditary predisposition to the disease

(Pearson). At the same time it must be remembered that such children are brought up in surroundings where they may receive massive doses of bacilli, as dealt with later. On the other hand, the long narrow chest, showing deficient apical movement, may predispose to phthisis. This is often a congenital characteristic. Experiments with animals have shown that the semen from tuberculous vesiculæ seminales or testes may in some cases produce a tuberculous foetus. Placental tuberculosis may also do the same, but these factors are of no importance as a cause of tuberculosis in later life.

Circumstances which favour the *acquisition* and rapid progress of the disease are those which expose the body to massive infections or seriously lower its vitality, whether these be a deficient supply of food and fresh air, or prolonged debilitating illnesses, or special toxic influences. The most frequent of these are—(a) overcrowding and deficient ventilation, working in close rooms in the fumes of gas, etc.; (b) deficient supply of food; (c) exhausting work; (d) exposure to damp and cold winds—Buchanan showed that amongst communities living on damp and imperfectly drained soils there was an undue proportion of deaths from phthisis and lung diseases; (e) excessive indulgence in alcoholic drink; (f) diabetes mellitus.

In the case of the lungs, (a) inflammatory lesions may prepare the soil for the growth of tubercle. This is particularly shown by the liability of tuberculosis of the lungs to follow pneumonia and the broncho-pneumonia of measles and whooping-cough. (b) Chronic irritation from the inhalation of dust particles (pneumoconiosis), which is described later. (c) Lack of blood supply, as in congenital heart disease, is also a factor predisposing to phthisis. On the other hand, it is noteworthy that in mitral stenosis, where the lung is chronically congested, phthisis is very rare.

The *age* of the individual is an important factor. The mortality is greatest during the first years of life, when the infection gains access through the lungs, and less often through the intestine. The mortality falls off rapidly during the second and subsequent years, and is at a minimum from the fifth to twelfth years. It then rises again, and there is a second maximum in early adult life. This second rise is due mainly to apical phthisis, the result of a re-infection after the original infection of childhood has died out (56).

3. Tubercle bacilli may enter the system by *breach of surface of the skin*, by the *genito-urinary tract*, by the *respiratory* passages, and by the *alimentary canal*.

The first two modes are rare and of no practical importance; but in the past persons performing post mortems have sometimes had their hands infected, contracting a post-mortem wart (*verruca necrogenica*), in which tubercle bacilli are found. Butchers occasionally contract similar lesions. They are very slowly progressive, and the tubercle very rarely spreads to other organs.

There has for a long time been a controversy as to the relative frequency of infection by the *respiratory* and *alimentary* tracts; the former is now held chiefly responsible. To answer this question we must first of all consider whether bovine or human tubercle is the commonest. (1) *Bovine* tubercle may be contained in milk from tuberculous cows and in tuberculous meat. The latter is not an important source of infection, because, apart from stringent regulations about its sale, meat is never eaten uncooked in this country. Infection by bovine tubercle will necessarily take place by the alimentary canal. (2) The researches of Cornet discovered the chief agent in the diffusion of *human* tubercle. It is not the air expired by the phthisical patient, but the sputum, which may be loaded with the specific micro-organisms. If this is repeatedly ejected on to the floor of a room and allowed to dry, or if quantities of it dry upon handkerchiefs, the air of the room may at length be sufficiently impregnated to become dangerous to healthy people breathing it. From the floor and walls of rooms formerly tenanted by phthisical people Cornet obtained bacilli by the inoculation of which he produced tuberculous disease in healthy animals. This helps to explain the

deadly influence of deficient ventilation in workshops, factories, barracks, and similar institutions. Human tubercle bacilli may thus be readily inhaled; but it does not necessarily follow that infection will take place by the lungs, because it has been argued that the bacilli and other dust particles are caught up in the mucus of the bronchi, are carried upwards by ciliary action or by coughing, and, reaching the mouth, are eventually swallowed, and so produce infection by the alimentary tract. However, experiment has shown that dust particles and bacteria can readily penetrate by inhalation to the inmost recesses of the lungs, and further that guinea-pigs and cattle can be more readily infected in inhalation experiments than when equal doses of bacilli are ingested. Again, in the industrial disease known as silicosis, which strongly predisposes to tubercle, the particles are obviously inhaled, because the lung and bronchial glands may be quite solid, while the mesenteric glands are hardly affected.

Several careful observations have been made on the frequency of bovine and human tubercle in different types of the disease and at different ages, the bovine variety being distinguished by its greater virulence on injection into rabbits. Bovine tubercle accounts for rather less than 1·5 per cent. of phthisis cases. On the other hand, in tuberculosis affecting the cervical and axillary glands 73 per cent. are due to bovine tubercle in children under ten, and about 30 per cent. in children over ten. Again, in tubercle of bones and joints, the percentage of bovine cases was found to be 28 per cent. under five years, 25 per cent. between five and ten, and only 9 per cent. between ten and sixteen (Griffith). Bovine infection is responsible for an average of 18 per cent. of genito-urinary tuberculosis in England (34). Fraser found a considerably higher percentage of bovine tubercle in surgical tuberculosis at Edinburgh, viz. 61·2 per cent. It is probable that variations occur in different localities. Tuberculous meningitis in children is most commonly secondary to caseous bronchial glands, and it has been found that over 90 per cent. of such cases are due to a primary tuberculous focus somewhere in the lungs (Ghon, Canti). This argues in favour of tuberculous meningitis being in most cases due to human tubercle, and this has been found to be so (Park and Krumwiede). In this connection mention must be made of some further work by Eastwood, F. Griffith and A. S. Griffith on thoracic tuberculosis in children. These authors found that out of sixty-six cases when the anatomical evidence was strongly in favour of infection by inhalation sixty-five were due to human and only one to bovine tubercle; however, in the north of England and Scotland, nearly 4 per cent. of cases of pulmonary tuberculosis are bovine, and 0·6 per cent. in the south of England (35). Out of twenty-three cases where the anatomical evidence was in favour of infection having taken place through the alimentary canal, eighteen were due to bovine and five to human tubercle. The conclusion from these figures is clear; it is that tuberculosis in adults is mainly of the human variety, but in young children a fairly large proportion may be due to bovine tubercle, and this will usually be the case if anatomical considerations point to infection by the alimentary tract. Further, from the relatively favourable course of cervical gland and abdominal tuberculosis in children we may draw the conclusion that bovine tubercle in man produces a milder disease than human tubercle.

The importance of infection from a human source has been shown in another way by Ward, working in rural and semi-rural districts in South Devon. In two series of all types of tuberculous cases at all ages 60 per cent. had been in contact with other tuberculous cases, whereas in a series of control non-tuberculous people only 12 per cent. had been in contact with tuberculous cases. The occurrence of conjugal tuberculosis pointed in the same direction: in 60 per cent. of cases where the husband or wife was tuberculous, the other partner also had tubercle. Similar results have been obtained from the study of children, who have lived with patients suffering from open tuberculosis, *i.e.* with patients constantly discharging bacilli from the lungs. It has been pointed out that the

danger to children does not lie so commonly in massive infection from parents, as the latter have been taught to collect and destroy the sputum, but in the unrecognised open tuberculosis of a grandparent, the nature of whose winter cough has never been recognised.

Morbid Anatomy. An elementary inflammatory focus caused by the *Bacillus tuberculosis*, which is too small to be seen by the naked eye, has the following structure: externally *lymphoid* cells, within these *epithelioid* cells, and in the centre a *giant cell*, with several nuclei formed by the enlarging of an epithelioid cell and divisions of nuclei inside the cell (36). These cells are connected together by a delicate protoplasmic network, and the characteristic *bacilli* are present in the body of the giant cell or lying between the epithelioid cells. Sometimes the giant cells are absent, sometimes also the epithelioid cells, so that the tubercle may consist only of lymphoid cells. As the tuberculous focus enlarges the cells undergo a process of coagulative necrosis from deficient vascular supply—for no vessel penetrates within the focus—and as a result of some chemical substance secreted by the bacilli.

A tubercle in its earliest stage, known as a *miliary* tubercle, is a translucent pearly grey nodule about the size of a millet seed, consisting of a central core of necrotic material surrounded by elementary foci. As it enlarges it becomes opaque yellow and cheesy in the centre, while at its periphery the tubercle may be invading more and more of the organ in which it is situated, the new tubercle becoming cheesy in its turn. In this condition it is known as a *caseous* tubercle. Under the microscope the caseous material shows shrunken cells, fat granules and *débris*. In the solid organs, large, spherical caseous masses are formed, as may be seen in the brain and spleen. If the disease invades a surface, vascular tuberculous granulation tissue is formed, similar to ordinary granulation tissue, but containing large mononuclear, epithelioid and giant cells, and sometimes well-formed tuberculous foci. Ulceration readily occurs. This may be seen typically in the intestine.

Some caseous masses ultimately undergo *calcification* (largely by formation of calcium phosphate), the tubercle bacilli are destroyed, and the lesion ceases to be infective. Another way in which tubercle terminates is by a *fibroid change*; chronic inflammation and induration of the surrounding tissue take place, and the tubercle itself shrinks into a fibrous nodule. This is more common on the surface of the pleura and peritoneum, but also takes place in the lungs.

Pathology. After the initial introduction into the body of tubercle bacilli the patient enters the primary tuberculous state, which is characterised by an epithelioid type of tissue reaction unaccompanied by allergy—e.g. hypersensitiveness to tuberculin. This period varies from two to ten weeks, usually averaging about six weeks. The patient may now recover completely, healing taking place by rapid calcification without the development of hypersensitiveness to tuberculin, or he may pass into the secondary state, which is characterised by the rapid development of a high degree of allergy (the intradermal tuberculin test showing a positive reaction to 0.1 c.cm. of 1/100 to 1/100,000 tuberculin). This early secondary allergic state may heal by resorption or may progress, breaking down the lymphatic gland defences to spread along the lymphatics or by the blood stream, and causing either metastases or generalised tuberculosis (miliary tuberculosis and caseous broncho-pneumonia). This generalised condition is described as the *late* secondary state. When recovery from the primary or secondary states occurs, there results a degree of immunity; if reinfection now takes place, the resulting condition, known as the “third state,” differs essentially from the two previous states. The high tissue immunity allows a localisation of infection to take place in the lung tissue; if the glands become involved (which is less likely) the infection is chronic, and not acute as in the primary state; fibrosis is a further evidence of high tissue resistance. This third state is adult “phthisis.”

TUBERCULOSIS IN CHILDHOOD

The pathology of the primary and secondary states of tuberculosis just described has a special reference to childhood, though it is also applicable to adults of native races, unaccustomed to tuberculosis, when they come among civilised peoples. Such was the case with North African troops when they were draughted over to Europe during the war.

Stomach Lavage. This has thrown a new light on the subject, because children always swallow their sputum. The technique is as follows: (1) 2 grains of potassium iodide are given three times a day for two days before the lavage. (2) The child is encouraged to cough first thing in the morning for twenty minutes. (3) He is then given 100 c.cm. of boiled water to drink. (4) Fifteen minutes later a stomach-tube is passed and as much fluid as possible withdrawn from the stomach. (5) This fluid is centrifuged and the deposit is treated with 1/10 antiformin (4 c.cm. diluted antiform being added to 100 c.cm. lavage). Alternatively, a 10 per cent. potassium hydroxide solution is added to the stomach lavage to make a final dilution of 1 per cent. This is allowed to act for an hour and then the whole is centrifuged. This method has the advantage of ensuring that the tubercle bacilli are not destroyed, but has the drawback that it leaves the deposit too thick for direct examination. (6) It is then injected under the skin in the abdominal region of the guinea-pig. (7) The guinea-pig is watched for six weeks, after which it is killed and examined for tuberculosis, both by direct smear of the diseased glands and by culture (37).

By this means it has been found that a number of children in the primary and early secondary states have tubercle bacilli in the sputum, *i.e.* have "open" tuberculosis. It is suggested that all patients go through a period of open tuberculosis sometime in this disease. In the late secondary state and in general tuberculosis, tubercle bacilli are found in the majority of cases.

Symptoms and Diagnosis. There is commonly a history of contact with a case of open tuberculosis. In the primary state X-rays may show a primary lesion in the lung. The "early" secondary state is often associated with loss of weight, fever, dry cough, pallor, and disturbances of the alimentary tract, while radiography of the chest may show enlargement of the hilum glands and sometimes "focal" lung reactions. At the same time certain so-called *paratuberculous* conditions, such as erythema nodosum, phlyctenular conjunctivitis, pleurisy and benign infiltration of the lung (epituberculosis) are apt to manifest themselves; the latter is shown by a uniform dense large area on the radiogram, described later, which can be differentiated from a lobar pneumonia by the characteristic shape of the latter and its disappearance in a week or so. Further progress into the late secondary stage of general tuberculosis is dealt with in the next section.

If healing takes place, the symptoms disappear and the only evidence left may be hilum shadows on the radiogram with *enlarged* and partly calcified *bronchial glands*—a combination known as hilum phthisis. Very occasionally these may press on surrounding parts, imitating an intrathoracic tumour, or suppurate, discharging into a bronchus with danger of causing asphyxia or broncho-pneumonia.

The **Prognosis** is favourable with proper treatment, even though tubercle bacilli have been found.

Treatment. This must be conducted on the same principles as that of tuberculosis in general. Rest in bed so long as the temperature is raised, good food, fresh air are the main requisites. Tonics, such as the syrup of iron iodide or of iron phosphate, Parrish's food, or cod-liver oil, may be given. The question arises as to whether these children should be regarded as infectious. Since tubercle bacilli only appear intermittently and are thus always swallowed, these children can quite well be treated with others in a convalescent home.

GENERAL OR MILIARY TUBERCULOSIS AND TUBERCULOUS MENINGITIS

Ætiology. This disease occurs at all ages, but is most frequent in children under two. So far as its causation is concerned, it is constantly associated with and secondary to more advanced tubercle elsewhere in the body. It may arise in the course of phthisis, hip joint disease, caries of the spine, or other tuberculous complaints. In many cases, especially in young children, the tuberculosis has been latent, as already described, and caseous bronchial glands resulting from a primary localised tuberculous affection in the lung, less commonly caseous mesenteric glands, are found at autopsy. Miliary tuberculosis is due to general dissemination of the infection by the blood stream, with the formation of miliary tubercles or minute tuberculous foci in any organ of the body. Such a spread may be due in a few cases to tuberculosis of the thoracic duct; but in the great majority a vein has been found eroded by an enlarged tuberculous gland, so that caseous material has been discharged into it, and quite suddenly the body has been flooded with numerous tubercle bacilli. These have been found in the blood after death and during life. This invasion is characterised by severe constitutional symptoms, presumably due to intoxication, particularly high temperature and rapid pulse. Sometimes several of these invasions may occur in a case, and this will be shown after death by the different sizes of the miliary tubercles in the various organs. Miliary tubercles are not large enough to interfere obviously with the functions of most organs. There are, however, two notable exceptions. Miliary tuberculosis of the meninges leads to interference with the functions of the brain, and to a less extent the same condition of the lungs interferes with its functions. The consequence is that, unless these organs are affected, miliary tubercle cannot be diagnosed with any certainty. It may be found accidentally at post mortem in a case where the symptoms have been ascribed solely to the primary lesion, whether in the lungs, as in phthisis, or in the kidneys, etc. For this reason it will be best to describe miliary tuberculosis and tuberculous meningitis together, the distinction between the two being noted in the appropriate places.

Morbid Anatomy. Through the *lungs* the tubercles are, as a rule, uniformly scattered more or less thickly. Every form of tubercle may be seen, from small grey dots to larger caseating tubercles; and sometimes these last may be breaking down in the centre, forming minute cavities. Definite patches of pneumonic consolidation occur, but are not common. Some inflammation of the bronchi, especially the smallest, is always present. Tubercles are sometimes found on the pleuræ, and pleurisy is often the result. In cases grafted on a former phthisis consolidation and cavities will also be present.

The characteristic appearances seen in the *meninges* consist of the presence of tubercles and of the effusion of lymph between the pia mater and the arachnoid. The lymph, which is gelatinous and translucent, or opaque and grey, or greyish yellow, but never purulent, consists of exuded fluid, fibrin, and lymphocytes in varying proportion. It is seen especially at the base of the brain, over the optic chiasma, the diamond-shaped space behind it, and the adjacent crura and pons. From this central point it commonly extends into the Sylvian fissure on each side, along the course of the middle cerebral artery, where it may be very abundant. The surface of the hemispheres is commonly free from lymph, or is at most a little dull or sticky, so that tuberculous meningitis is often called a *basal* meningitis; but it is common to find a small patch of lymph at the top of the cerebellum, at the anterior part. With the lymph are commonly mixed tubercles, varying from mere points up to the size of millet seeds, and occasionally beginning to caseate. The tubercles are especially abundant on the pia mater in the fissures of Sylvius. Under the microscope the smaller tubercles present aggregations of lymphoid corpuscles in the perivascular sheath; the larger tubercles may present all the characteristic features; but usually giant cells are absent.

The relation of the inflammatory lymph to the tubercles is very variable. There may be abundant lymph in the characteristic situations, with few, if any, tubercles discoverable; there may be a good number of tubercles with very little lymph. The ventricles of the brain are commonly distended with fluid (whence the old name *acute hydrocephalus*); the convolutions are flattened against the skull; the brain tissue is soft and often obviously congested. The cranial dura mater is not usually affected, but the spinal dura mater sometimes shows minute tubercles, and the lymph in the pia mater may extend to the cervical region of the spinal cord.

Miliary tubercles are also usually seen in and on the surface of the liver, kidneys, and spleen; while less often the choroid of the eye, the heart, thyroid, bone marrow, and peritoneum are involved. Any organ of the body may be affected, and no organ is invariably so. Sometimes the meninges may be apparently to the naked eye alone affected, but it is probable that microscopic examination would in such cases disclose evidence of infection in other organs as well.

Symptoms. There is often a prodromal stage, during which the child is out of health, restless, loses appetite, gets thin, may be occasionally sick, and has constipation. The illness begins more definitely by headache or vomiting, or perhaps a convulsion. The headache is severe and continuous, with exacerbations from time to time; the child puts its hand to its head, and may be often crying, "Oh, my head!" or simply whining, or moaning, or occasionally uttering a sudden short shriek. With this there is a moderate degree of fever, quick pulse, excessive sensibility to light and sound, so that the child shuts the eyes, and desires to be left alone in bed; it resents being disturbed, and often curls itself up in bed away from intruding friends. The vomiting does not generally last long. If the illness begins with a fit, this is not often repeated. Occasionally there is squint, and there may be diplopia quite early.

After a few days, still with severe headache, there may be slight delirium, and the patient becomes drowsy. The head is sometimes retracted, and the neck is stiff; the abdomen becomes hollowed or retracted, the outlines of the muscles are obvious through the skin, and the margins of the ribs and the iliac crests are prominent. For this the terms *carinated* and *boat-shaped* are sometimes used. Kernig's sign is sometimes present. The pulse may be slow, and is often irregular; the respirations are slow, sighing, and irregular; the temperature is still generally high, or oscillates between 101° and 103° , but it may be extremely irregular, and sometimes the *typus inversus* is present, the morning temperature being high and the evening low. When the finger is drawn sharply across the skin of the forehead or abdomen, a broad red line quickly appears, and may persist five minutes or more. This condition, which is not peculiar to, but only more marked in, meningitis, is called *tache cérébrale*. Even as early as this, changes may often be observed in the optic disc, which at first becomes highly vascular, and then shows definite optic neuritis. Tubercles are seen in the choroid in a small proportion of cases. Usually some pulmonary symptoms are present; there is cough, and râles may be heard in the chest. Yet it is remarkable how full of minute tubercles the lungs may be without producing any physical signs.

From this point the case may steadily go on to a fatal termination without any fresh symptom. Food is taken badly, and the bowels are constipated. The drowsiness increases to coma, optic neuritis is more pronounced, the abdomen becomes more and more hollowed, the pulse more irregular, feebler, and generally quicker, and Biot's respiration may be seen (*see* p. 121), and the temperature may fall more or less rapidly, or just before death go up quickly to 106° or 107° . Mucus accumulates in the bronchial tubes, and with failing pulse death takes place. But often the last few days are marked by local symptoms, paralysis of a limb, squinting, or ptosis. The pupils are frequently unequal, and one or both may be insensitive to light. Frequently this stage is marked by convulsions, and

these may recur several times before death. Sugar is sometimes found in the urine in the last few days. The illness lasts from ten days to four, five, or six weeks. The above course of the disease has been divided into three stages: a stage of *irritation*, one of *compression*, and the last a *paralytic stage*. But it is not always easy to distinguish between them, and in some cases the more typical symptoms may be very little marked, coma alone being prominent.

In the tuberculous meningitis of adults the symptoms are often much more rapidly developed. The onset may, of course, be masked by those of the disease already existing, *e.g.* phthisis. The patient may, with very little warning, become delirious, and have paralysis of a limb or of the face, or have a fit, quickly becoming comatose, and dying within a few days. Retention of urine has sometimes been observed as the first sign of meningitis in such cases.

The cerebro-spinal fluid in the early stages is quite clear, though it may be under considerable pressure; a "spider" clot may form in the tube. Later it is faintly turbid, but never purulent. It contains an excess of lymphocytes, and sometimes tubercle bacilli may be detected. For other features, see Cerebro-spinal Fluid.

In cases of general tuberculosis without involvement of the meninges, or when this occurs only in the last stages, the symptoms may be very obscure most of the time. The patient complains of weakness, inability to do his work, loss of flesh, anorexia, nausea or sickness, and headache. The bowels may be constipated or occasionally loose for a few days. Irregular pyrexia is present. The pulse is rapid and feeble and the tongue dry. In proportion as the course is prolonged the tubercles in the lungs grow, break down and produce prominent symptoms. There are cough, dyspnoea, scanty mucous expectoration, tinged, it may be, with blood, and sometimes pain in the side. The physical signs are at first suggestive of bronchitis, and later broncho-pneumonia. When this is well marked the patient presents a high degree of cyanosis, the face, lips, nose, ears, and cheeks being livid, and the fingers shrunk and blue. Death at length takes place, after from three to eight or ten weeks, with increasing dyspnoea, lividity, prostration, and drowsiness. Meningitic symptoms may supervene at any time.

The characteristic features in tuberculous meningitis are, the insidious onset, pulmonary symptoms when present, headache, irritability leading on to drowsiness and coma, and the early involvement of the cranial nerves; choroidal tubercles when present are pathognomonic. The disease must be distinguished from other forms of meningitis and so-called meningism and other forms of intra-cranial disease, such as tumour, abscess and thrombosis of the cerebral sinuses. There is no real difficulty, because the clear cerebro-spinal fluid in tuberculous meningitis, with its increase of lymphocytes, is quite characteristic; the sugar disappears and the chloride content is lowered. In many other types of meningitis the onset is abrupt, as in cerebro-spinal fever, or there is an obvious primary focus, as in suppurative meningitis following otitis media or other condition; the cerebro-spinal fluid is definitely turbid and contains polymorphonuclear leucocytes. Pronounced opisthotonus and a marked Kernig's sign are more in favour of cerebro-spinal than of tuberculous meningitis. Acute poliomyelitis or encephalitis lethargica might cause a difficulty; in the former disease the onset is abrupt. In cerebral tumour and abscess the temperature is not usually much raised, and the pulse may be slow.

Prognosis. Tuberculous meningitis is a very fatal disease, but undoubtedly a few cases in which tubercle bacilli have been found in the cerebro-spinal fluid have recovered. But these few cases do not alter the absolutely unfavourable prognosis that should be given when once the nature of the disease is known. On occasions there may be for a time a remission of symptoms. Much the same thing applies to miliary tuberculosis without meningitis.

Treatment. This should be directed to the relief of symptoms. Lumbar puncture is the most effective measure; it relieves the headache, and temporarily

alleviates the symptoms, and may be performed daily. Owing to photophobia the rooms should be darkened.

GLANDERS

(*Equinia, Malleus, Farcy*)

Glanders is a disease which affects chiefly horses, mules, and asses, though sometimes other domestic animals, and is occasionally transmitted accidentally to man. Grooms, stablemen, and others in charge of horses are most liable to contract the disease, which in its acute forms is a febrile disorder, characterised by special lesions of the nasal and respiratory mucous membranes, by the formation of subcutaneous nodes and the implication of the lymphatic vessels and glands, and by a cutaneous eruption. It also occurs in a chronic form. The term *farcy* was given to cases in which the subcutaneous nodules (*farcy buds*) with the lymphatic lesion were prominent features; but it is not desirable to have two names for one disease, and glanders is now the appellation generally adopted.

The disease is mostly transmitted to man by accidental inoculation of wounds, cuts, or abrasions, either in grooming a glandered animal or in skinning one dead of the disease, or a horse may bite its groom and convey the disease by means of its saliva, or may sneeze and discharge some nasal mucus into the eye, nose, or mouth of any one standing near. It is stated that it may be conveyed by eating the raw flesh of a glandered animal, and that it has been caught in this way in menageries. It may also be communicated from man to man. The bacillus of glanders (*B. mallei*) is found in the nodules; it is about the size of the tubercle bacillus, but is thicker and is decolorised in Gram's method.

Pathology. On post-mortem examination in acute glanders the changes characteristic of pyæmia are often found: increased fluidity of the blood and abscesses of the lungs, the pyæmia being secondary to the local lesions.

The characteristic lesions of glanders are found in the mucous membranes, the skin, and the lungs. In the nasal mucous membrane, subepithelial nodules occur, from the size of a millet seed to that of a pea, consisting of lymphoid corpuscles or pus corpuscles. In a later stage these nodules have suppurated, and left ulcers with yellowish bases. Around these fresh nodules of infiltration have formed, which go through the same process. The septum may be perforated. If recovery takes place, irregular puckered scars are left. In the lungs, similar nodes form, the centres of which break down into a caseous detritus. These are accompanied by patches of broncho-pneumonia, which may form abscesses. Similar nodes form in the conjunctivæ, frontal sinuses, pharynx, larynx, intestines, skin, subcutaneous tissue, and muscles.

Symptoms. *Acute Glanders.* The disease begins with malaise, headache, lassitude, loss of appetite, and pains in the joints and limbs. For a time there is often a resemblance to rheumatic fever or enteric fever, or there may be pain in the side or dyspnœa. If a wound or scratch has been infected directly, it becomes inflamed, tense, and painful; and the skin around has the appearance of erysipelas. The sore ulcerates, and discharges a sanious fluid, and the lymphatics in the neighbourhood may become enlarged. The more characteristic features of the disease may not appear for a week or more after its commencement, though sometimes earlier. The *eruption* consists of small red papules, upon which vesicles appear; these soon form bullæ, or pustules, of different sizes, up to $\frac{1}{2}$ or $\frac{3}{4}$ inch in diameter, hemispherical, flat or depressed in the centre, with serous, purulent, or blood-stained contents. The base of the pustule is inflamed, and infiltrated for some distance round. After a time the discharge escapes, and an ulcer covered with scab or slough remains. The *nodes* which form under the skin are at first hard and painful, and generally suppurate. The lymphatic glands are not always inflamed. The implication of the mucous membranes is shown

by a discharge from the nose, which is at first a thin mucus, but afterwards becomes thick, viscid, purulent, foetid, and often blood-stained. It is connected with the formation of the tubercle-like nodules already described.

Usually the disease progresses steadily, with symptoms of a pyæmic character. The temperature is high, but may oscillate; the pulse is quick, and the tongue dry and brown. Albumin appears in the urine, low delirium with tremor is succeeded by coma, the breathing becomes more rapid, and death finally ensues, generally in two or three weeks from the commencement.

Chronic Glanders. Here the local lesions predominate. They consist of ulcers with thick and hard edges, or abscesses about the joints, or inflammatory swelling beneath the skin or in the muscles. A pustular eruption may also occur, but it develops more slowly than in the acute form. The nasal mucous membrane may also be involved, and in some cases emaciation occurs, with hoarseness and pulmonary symptoms, such as cough and hæmoptysis. The average duration of the chronic cases is stated to be four months.

Diagnosis. In early stages the disease may be mistaken for rheumatism or typhoid fever, and later for pyæmia. In chronic cases, syphilis, scrofula, and phthisis may be simulated. In veterinary surgery, the diagnosis is made by the injection into suspected animals of *mallein*, which consists of the chemical substances present in the artificial cultures of the glanders bacilli. If the animal is diseased, a definite "reaction" with rise of temperature occurs, similar to that produced in man by Koch's *tuberculin* (see Diagnosis of Phthisis).

Prognosis is very unfavourable. Only a few recoveries from acute glanders are recorded, and only about half of the chronic cases get well.

The **Treatment** must be supporting and stimulating. Quinine should be given internally; the nasal lesion should be treated with antiseptic injections, such as creosote, carbolic acid, iodine or potassium permanganate lotion. Abscesses of the skin should be opened when ready. For chronic cases carbolic acid, potassium iodide, arsenic, strychnine, and sodium benzoate have been recommended.

ANTHRAX

This term, formerly the Latin equivalent of *carbuncle*, is now generally used to designate a disease which affects various animals, and is communicated from them to man. In animals it is known as *splenic fever*; in man it includes *charbon* of the French, and *malignant pustule* of English writers. Its distinguishing feature is the presence of a bacillus (*B. anthracis*), which can be found in the local lesions, the blood, viscera, and secretions. This is a non-motile, Gram-positive bacillus, varying from 5μ to 20μ in length—that is, considerably longer than the diameter of a blood corpuscle. The bacilli multiply by elongating and dividing. Outside the body they may produce spores within themselves, which subsequently become free. The spores have great vitality, and resist considerable changes of temperature; they reproduce bacilli in a favourable environment.

Infection in man occurs from the living animal, as in drovers, shepherds, and farmers, or from the carcase, and this is much more common. Thus slaughterers, butchers, and those who have to do with the hides may be infected through a scratch or wound, and rarely it may be contracted in eating the flesh of diseased animals. Most frequently, however, in England it occurs amongst tanners and those who have to handle the skins and hides that come from abroad, and among those who deal with wool and hair from the same animals. Thus wool-sorters, furriers, tanners, and others in like occupations may contract the disease either by direct inoculation through the broken skin, or by inhalation of dust or wool particles proceeding from the goods. It is twice as common in the winter as the summer months (58). Some cases have arisen from the use of shaving brushes, especially those of Japanese manufacture, made of animal hair infected with anthrax. Rarely it is transmitted from man to man by direct

contact. Rag-sorters engaged in paper manufactories are subject to pulmonary anthrax, and the bacillus of anthrax has been found in the viscera.

Morbid Anatomy. In all fatal cases there may be found the changes indicative of acute septic disease: ecchymoses in the submucous and subserous tissues, in the substance of the heart, or in other muscles; hæmorrhage or œdema of the lungs; congestion and softening of the liver and kidneys. The spleen is not always enlarged. When the special *pulmonary* symptoms have been present, there are congestion of the mucous membrane of the trachea and bronchi, hæmorrhages into the lungs or under the pleura, swelling of the cervical and bronchial glands with hæmorrhage into or around them, fluid in the pleural cavities, and ecchymosis and gelatinous exudation in the neck and mediastinum surrounding the trachea and mediastinal glands.

In the *intestinal* form the peritoneum contains serum, which is often blood-stained; there is semi-gelatinous infiltration of the mesentery and retroperitoneal connective tissue; congestion and swelling of the mucous membrane and submucous tissues of the stomach and intestines in patches of $\frac{1}{4}$ inch to 1 or 2 inches in diameter, which are pink and fleshy on section, but on the surface discoloured, or excoriated, or covered with an adherent layer of blood. There are also submucous and subserous hæmorrhages, and the spleen and the mesenteric and lumbar glands are often enlarged.

Some cases of hæmorrhagic *meningitis* have also occurred.

Symptoms. The different forms of the disease are local or external anthrax—*malignant pustule* proper—and *anthrax septicæmia*, which includes a pulmonary and a gastro-intestinal form. Either of the last two may be combined with the local variety.

Malignant Pustule. Infection generally occurs through a scratch or abrasion on the face, neck, hands, or arms. After an *incubation* of a few days, or it may be only some hours, the spot itches or burns, and a small patch of erythema appears, a little larger than an ordinary flea-bite with a minute vesicle on top. This gradually enlarges and bursts, discharging a thin fluid. The base of the vesicle then forms a brown or black eschar, and the skin around becomes red, swollen, and indurated, forming a prominence from $1\frac{1}{2}$ to 2 inches or more in diameter. Around the central eschar there is often a ring of small vesicles containing serum, and the skin for some distance round may be œdematous, and the nearest lymphatic glands enlarged and tender. However, in most cases the pustule has not this characteristic appearance, but resembles vaccinia. For three, four, or five days the patient may feel in his usual health and continue at work; he then becomes feverish, with prostration, delirium, sweating, or diarrhœa; and finally, in many cases, death occurs, preceded by collapse. In *malignant anthrax œdema* no definite pustule forms, but an œdematous swelling, usually affecting the eyelids. It is otherwise like malignant pustule, and is mostly soon fatal.

Anthrax septicæmia varies in different cases. The early symptoms are generally restlessness, a sense of depression and exhaustion, and vague sensations in the limbs; then acute fever suddenly sets in with the usual symptoms, and, in addition, great prostration, embarrassed respiration, and rapid collapse. In the cerebro-spinal fever epidemic of 1915–16, the symptoms of this disease were simulated by five cases of anthrax septicæmia, the bacilli being found in the cerebro-spinal fluid (Reece).

In the *pulmonary* form difficult and laboured breathing with a sense of constriction, cyanosis, and great prostration, are the main features, without much cough or physical signs other than a few rhonchi and râles. The expectoration, if there is any, may be bloody. Delirium and coma may precede death, or the mind may be clear to the last. This is the *wool-sorters' disease* observed at Bradford and elsewhere.

In the *gastro-intestinal* form there are vomiting, abdominal pain, and diarrhœa, often with blood in the fæces, sometimes dysphagia and bleeding from the

pharynx and mouth. Fever is slight, but dyspnoea and lividity, restlessness and convulsions of epileptic or tetanic character, precede the invariably fatal end.

Diagnosis. The diagnosis of cutaneous anthrax is easy in quite an early stage, if only the practitioner thinks of the possibility of anthrax. All that is necessary is to examine a stained smear from the vesicle under the microscope. But it may be missed, because the lesion may be thought to be just a pimple. In a later stage it resembles vaccinia. In pulmonary and gastro-intestinal anthrax the diagnosis is much more difficult. But an unusual combination of symptoms, such as vomiting and joint pains, may arouse suspicion. Bacilli may be detected in the blood, vomit, expectoration, urine or cerebro-spinal fluid. But they are not generally to be found in the blood for some days. The diagnosis may be confirmed by inoculation of a rabbit, guinea-pig, or mouse with the secretions or with blood. The animal dies within two or three days with dyspnoea, dilated pupils, and, perhaps, convulsions; and the blood contains the characteristic bacilli.

Prognosis. In Bradford, where special precautions have been taken to make an early diagnosis, the mortality has been lowered from 16 to 5 per cent. A localised pustule indicates resistance to the bacillus; a widespread œdema suggests that resistance has broken down.

Treatment. In malignant pustule the correct treatment is complete surgical excision in the early stages; but this should not be carried out if the lesion has progressed much beyond the "flea-bite" stage, as is usually the case when the diagnosis is made. The part must be rested by means of splints or sand-bags and antiseptic dressings applied. It is also important to administer anti-anthrax serum, such as Selavo's, at the earliest possible moment: 150 to 300 c.c. are injected intravenously, to be repeated on the day following, if there has been no reaction (shown by a rise of temperature) and the general condition has not improved; 10 c.c. serum are injected locally just outside the blanched zone every four hours. In default of serum, novarseno-benzol should be used, 0.6 to 0.9 gram on the first and second day, and again on the fourth day if necessary; the worse the case the larger the dose given. The temperature may remain high even though the bacilli have disappeared from the wound.

TETANUS

In this disease, of which the name is derived from *τετέρω*, I stretch, the essential condition is the occurrence of tonic contractions of most of the muscles of the body with paroxysms of increased contraction from time to time. It is due to a bacillus (*B. tetani*), which exists in different forms of earth or garden mould, and which will cause tetanus in animals when such earth is inoculated under the skin.

The bacillus measures 4μ to 5μ in length, and 0.4μ in thickness, is flagellated, and stains with the usual dyes and with Gram's method. It produces spores which are developed at one end, and, having a diameter larger than that of the bacillus, give it the appearance of a drumstick. It grows anaerobically.

Ætiology. The disease occurs in quite young infants (*tetanus neonatorum*), and after that age at all periods of life from five years upwards. It is more common in hot countries, and the dark-skinned races seem especially liable to it. A very frequent antecedent is injury (*traumatic tetanus*), by which an entrance is provided for the bacillus. This may be of any kind, from a mere scratch with a pin or nail to the most serious compound fracture or lacerated wound; but infection is especially liable to take place when the wound has been contaminated by contact with earth, dirt from the road, garden mould, stable straw, or similar materials. In fact, a suspension of washed tetanus bacilli or their spores can be injected into animals without harm; but if calcium chloride or hydrated soluble silica, both of them common constituents of soil, be injected at the same time, the organisms grow and produce the disease. Tetanus has

followed the subcutaneous injection of gelatin for aneurysms and of quinine for malaria. In new-born infants the organism enters by the cut surface of the umbilical cord. Probably, in all cases formerly called *idiopathic*, some means of local infection was overlooked. For instance, a stableman with otorrhœa acquired tetanus, no doubt, because he infected the meatus and tympanum with his finger soiled with stable dirt. The disease is sometimes epidemic.

Morbid Anatomy. Many cases present after death no pathological lesions whatever. The organs most commonly affected are the lungs, which may be the seat of pneumonia, bronchitis, œdema, or hæmorrhages. The central nervous system, as a rule, looks normal to the naked eye, or at most shows some hyperæmia of the grey matter. Microscopical examination may also show slight degenerative changes in the nerve cells. Both these conditions are referable to the action of toxins, or to the vascular disturbance during the spasms. The muscles of the trunk, especially the abdominal muscles, are sometimes ruptured or the seat of hæmorrhages. In traumatic cases the state of the wound bears no relation to the final result—it may be healing, or healed, or suppurating, or sloughing.

Pathology. The bacillus multiplies chiefly in the neighbourhood of the wound, and produces poisons which have an affinity for the central nervous system, especially the spinal cord. They have, however, been found in the lymphatic glands.

Experiments on animals also show that such toxins are absorbed into the blood ; but they are also taken up by the end plates of the nerves in the muscles, and are transmitted by the axons of motor nerve fibres, or by the lymphatic vessels accompanying them, to the cells of the corresponding anterior cornu ; and this appears to be the chief means by which the nerve centres are infected. If the toxins are sufficient, they are carried to the opposite cornu, and to other parts of the cord. Nevertheless in unprotected man the muscles first attacked by spasms are not generally determined by the seat of injury, but are usually those of the back of the neck and of the jaw. Tetanus has also been transmitted from man to animals by the inoculation of materials from the wound, and by the injection of urine which contains the toxin.

Symptoms. There are two distinct clinical types of tetanus: (1) the classical type of “pre-serum” days, characterised by trismus being the initial symptom; (2) modified tetanus, a discovery of the recent war, which may occur in patients who have had a prophylactic injection of anti-tetanus serum.

The Classical or Generalised Type. The period of *incubation* between the infliction of the wound and the onset of symptoms is from one to thirty days, about half the total number of cases developing during the second week and one-third during the first week. It is found that the incubation period is delayed in prophylactically immunised patients who contract this type of disease. The patient feels stiffness first in the jaws, so that he is unable to open his mouth wide, or to masticate properly. There is also stiffness at the back of the neck. He may continue like this for a day or two, or may rapidly pass on to the next stage, in which there is rigidity of the muscles of the trunk and to a less extent of those of the extremities. The back becomes rigid, and is slightly arched, with the concavity backwards (*opisthotonus*) ; the muscles of the trunk and abdomen become quite hard from constant contraction ; the movements of the chest are limited from the same cause ; the legs are generally rigid, but the arms are only rather stiff about the shoulders and elbows, and the fingers may be moved freely. By this time the jaw is generally firmly fixed by contraction of the masseters, and the teeth cannot be separated for more than $\frac{1}{4}$ inch (*trismus*, or lockjaw, by which last name the disease itself is popularly known) ; the angles of the mouth are drawn outwards, and the lips are slightly separated ; the eyebrows are drawn up by the frontal muscles, and together by the corrugators, so that the facial expression is that of a painful grin, known as the *risus sardonicus*. When this stage has

been reached, the so-called "spasms" or paroxysms of increased and even violent muscular action begin. These consist of sudden contractions involving the whole of the muscles hitherto in tonic rigidity. The teeth are clenched more violently, the *risus* becomes more marked, the head is thrown back and the back arched more strongly, the chest is fixed, and the respiratory process is checked; a groan may escape from the patient, either elicited by pain or the result of expiratory spasm. The paroxysm is often of momentary duration, scarcely to be counted in seconds, and the patient relapses into his former condition of tonic contraction, or it may last several seconds, the face and hands become more and more livid and swollen, and there is imminent danger to life from the hindrance of respiration. It is always intensely painful; it is brought on by external impulses, by touching the patient, jerking his bed, by passing a catheter or giving a subcutaneous injection. The paroxysms occur at first at intervals of half an hour, an hour, or more, but as the disease progresses unfavourably they become more violent, and occur at shorter and shorter intervals. Between the spasms there is still some pain from tonic contraction, respiration is not entirely free, and the voice is feeble. The reflexes are increased. The pulse is small and quick, and becomes quicker during the paroxysms. The temperature generally at first remains normal, and may continue so to the end, though it sometimes rises a little before death; sometimes the temperature is constantly above normal; in other cases a hyperpyrexia of 107° or 108° occurs just before death, and the temperature has been observed to continue rising even after death to 110° . The urine is often retained, so as to require the use of the catheter. Sensation is generally unaffected, and the cerebral functions are mostly quite normal until near the end, when delirium may occur. In a great number of cases the disease progresses to a fatal termination in from one to twelve days: the paroxysms become more violent and frequent; and death takes place from exhaustion, or from spasm of the glottis, or from fixation of the respiratory muscles; or pneumonia or bronchitis adds its influence against the patient. As happens both in fatal chorea and in hydrophobia, the muscular contractions sometimes entirely cease for eighteen or twenty-four hours before death. In a few cases life is prolonged to the third or fourth week. On the other hand, recovery may take place: the spasms, having reached their height, gradually become less frequent; the constant rigidity of the muscles subsides, and the patient is convalescent in from three to six or eight weeks. Occasionally a case runs its whole course to a fatal termination with general rigidity, but without any paroxysms in addition; and very rarely there are paroxysms without the continuous spasm.

Modified or Local Tetanus. In this form the incubation period is lengthened, being over three weeks in about half the cases. The disease is limited to the muscles which are close to the wound. Thus one arm may be affected, or one or both legs, or the abdominal muscles when the wound is in the abdomen. The affected muscles may show tonic or clonic spasms, or there may be rigidity and hardness of the muscles, with inability to move them. The contractions may be extremely painful. Local tetanus may spread after some days. Thus if one limb is affected the disease may later on involve the other one. It may also become generalised, causing trismus and reproducing the classical form of the disease.

Some special types of local tetanus are described. Thus the name *splanchnic tetanus* has been given to cases which arise after lesions of the viscera, such as penetrating wounds of the abdomen or thorax. It is nearly always rapidly fatal: the spasms are confined to the muscles of deglutition and respiration; and the difficulty of swallowing may be so great that the case closely resembles one of hydrophobia in the liability to pharyngeal spasms at the sight, or even mention, of a glass of water. This is usually accompanied by dyspnoea.

The name *cephalic tetanus* is given to cases which arise from injuries to the head or face. Of this variety four forms are described: (a) one in which there

is no paralysis, but in which dysphagia and dyspnœa may be present, and the dysphagia may reach such a degree as to resemble closely hydrophobia ; (b) another, ophthalmic tetanus, in which the oculomotor nerve is involved, causing ptosis, or paralysis of the ocular muscles, extrinsic or intrinsic ; (c) a third rare form, in which the hypoglossal nerve is concerned ; and (d) the fourth, in which the facial nerve is affected, facial paralysis occurs, and spasms take place in the paralysed muscles.

Diagnosis. Tetanus may have to be distinguished from strychnine poisoning, hydrophobia, spinal meningitis, tetany, muscular rheumatism, and hysteria. In *strychnine poisoning* the extremities are involved to a much greater extent than in tetanus, and the paroxysms are excited by external stimuli ; but in the intervals the muscles are relaxed. The symptoms develop very rapidly, but do not begin with trismus. In *hydrophobia* there is no continuous rigidity ; the spasms involve the respiratory muscles, and are excited by the attempt to drink or the sight of fluids. Mental agitation or even maniacal excitement is generally present. In *spinal meningitis*, again, trismus is not an early symptom, nor is there constant rigidity ; muscular spasms are excited by attempts to move, and the temperature is high from the first. The early occurrence of cerebral symptoms would be opposed to tetanus. The peculiar distribution of the spasm in *tetany* makes it easy to distinguish it from tetanus. *Muscular rheumatism* may cause stiffness of the back of the neck, which might, under certain circumstances, cause alarm ; but trismus is never present. In severe forms of *hysteria* opisthotonus is often a prominent feature, but it occurs as part of a series of convulsive movements, which cannot be mistaken. The local form of tetanus affecting one limb must be distinguished from a hysterical paralysis.

Prognosis. The shorter the incubation period the greater the mortality. In pre-serum days the mortality was between 80 and 90 per cent. of all cases as judged by several independent series of observations. During the late war the average mortality of all the English cases was 50·8 per cent., this reduced rate being accompanied by a considerable increase in the incubation period. This was due to the introduction of prophylactic serum injections. Analysis of the whole series of cases indicated that there was no evidence that curative serum injections had any effect in reducing the mortality (Golla). The mortality of purely local tetanus was practically *nil*.

Prevention. All wounds should be promptly cleansed or excised ; antiseptics, even strong carbolic acid, may be usefully employed to diminish the chance of infection. In warfare and in civil life, if the wound is deep or lacerated or contaminated with mud or earth, 500 units of tetanus antitoxin should be injected subcutaneously as early as possible : and as the protection conferred by this dose seems not to last more than ten days, a second injection should be given after seven days in cases of septic wounds, and in exceptional cases a third or even fourth at the same interval. The antitoxin has been applied locally to wounds in similar circumstances. In the event of secondary operations having to be performed, Leishman and Smallman recommend injections of antitoxin around the site of the operation, if possible, forty-eight hours before the operation, and to the extent of about 1,500 units. They suggest also injection into the sheaths of the prominent nerves.

Treatment. The patient should be kept at rest, and is best placed in a darkened and perfectly quiet room, so as to avoid all impressions of sight and sound. The closure of the jaws may necessitate food being given by a nasal tube. If a wound is present, it should not be actively interfered with until the tetanic symptoms have subsided, as fresh toxin may be liberated.

The curative action of serum has been much discussed. Statistics suggest that serum is not of much use ; but these are not very satisfactory, as the matter is complicated by the very favourable influence prophylactic injection has upon the mortality. Experimental evidence points strongly to the fact that serum

may do good if given early, and further that the correct route is by the spinal canal. Thus Sherrington found that there were fourteen recoveries out of twenty-five monkeys which had been injected with tetanus toxin and received an intrathecal injection of antitoxin forty-seven to seventy-eight hours later, *i.e.* after the first symptoms of tetanus had shown themselves. When the same dose of antitoxin was given subcutaneously the recovery rate was two out of twenty-five; when given intramuscularly it was three out of twenty-five; when given intravenously it was seven out of twenty-five; when given subdurally through the skull it was none out of ten. On the other hand, when it was given intrathecally through the atlanto-occipital membrane the recovery rate was thirteen out of twenty. In view of the uncertainty attaching to the results of serum treatment in the war, it will be safest to take these experiments as the guide to treatment. They point to the importance of intrathecal injection of serum in the first place, and of intravenous injection in the second place. These must be carried out at the earliest possible moment, and a general anæsthetic must be given to prevent anaphylaxis. The serum should be allowed to run slowly into the theca under gravity through a funnel after withdrawing some cerebro-spinal fluid. The present tendency is to give large doses of serum intrathecally (cisternal puncture has been used), intravenously and intramuscularly; as many as 700,000 units have been advocated for a case (32). Intrathecal injections of magnesium sulphate (1 c.c. of a 25 per cent. solution for every 10 kilogrammes of body weight) have also been used. The contractions may be abolished, but it is doubtful if the injections reduce the mortality. Curare has recently been used and the results are promising. If necessary, the patient should receive sedatives, *i.e.* avertin; chloral hydrate, 30 to 60 grains by mouth; chlorotone, 10 to 15 grains by mouth or 30 to 40 grains dissolved in olive oil *per rectum*. In a case of generalised tetanus treated successfully by A. Taylor at Lewisham Hospital 214,000 units were given intramuscularly between the sixth and 17th days after the wound, and 120,000 intravenously on the sixth, seventh and eighth days, 334,000 units in all. In addition the boy had 60 grains of chloral and 120 grains of potassium bromide in twenty-four hours.

If respiration ceases owing to spasm of the respiratory muscles Drinker's respirator or the Bragg and Paul apparatus or rocking method should be used as described under Acute Poliomyelitis.

GAS GANGRENE

This is an infection of the tissues by certain gas-forming anaerobic bacteria.

Ætiology. Gas gangrene was common in the pre-antiseptic days. It became very rare in hospitals after antisepsis and asepsis were firmly established, but was met with again frequently during the recent war, where the bacteria which are often present in dirt gained access to the tissues through gunshot and, particularly, shell wounds. Several different bacteria are found, but the most important are *Bacillus perfringens*, which is the same as the *B. aerogenes capsulatus* of Welch, *B. œdematiens* and *Vibrion septique*.

Symptoms. In the early stages the skin looks normal. Then the limb swells and the skin becomes tense. As gas accumulates a resonant note is obtained on percussion and there are crepitations. Areas of purple staining appear and coalesce, and there are blebs containing fluid, stained by altered blood. Finally, the purple gives place to a dark yellow-green tint.

Diagnosis. X-rays provide the earliest means of diagnosis. Clear areas corresponding to collections of gas are seen in radiograms. They tend to be arranged along the muscle fibres.

Prognosis. This is practically hopeless, unless early energetic treatment is adopted.

Prevention. This consists in the excision of contaminated wounds, and in the prophylactic injection of specific anti-serum.

Treatment. This is chiefly surgical, and consists in the excision of the affected muscles or amputation. Good results have been obtained experimentally with serum injections (Bull).

Diseases Due to Fungi (Mycoses)

Fungi are filamentous plants of simple cellular structure composed of two distinct parts—mycelia and spores. Their classification is at present very difficult (59). The parasitic dermatomycoses are described elsewhere.

ACTINOMYCOSIS

Actinomycosis is the name given to a granulomatous lesion from which typical "sulphur granules," visible to the naked eye, are obtained. It is due to the ray fungus, which belongs to the streptothrix group, and is known as *Actinomyces bovis* (Wolff-Israel). In 1877 Israel, of Berlin, described the first cases in man, and in 1878 Ponfick showed the identity of the human cases with the cases occurring in cattle.

The actinomyces form masses which are visible to the naked eye as yellow, greenish-yellow, or grey, glistening, spherical, granular bodies, the "sulphur granules," mostly about $\frac{1}{2}$ to 1 mm. in diameter, and consisting, under the microscope, of a central mass of closely woven mycelial threads and an outer layer of "club"-shaped bodies arranged radially and giving the appearance of "rays," from which the organism gets its name. The whole is encased with leucocytes. The organism grows anaerobically and is non-acid fast.

The *Actinomyces bovis* is a saprophyte in the mouth, growing, in particular, round septic teeth. It gains entrance owing to injury of the mucous membrane, and this may be caused by a foreign body, such as a barley corn or piece of straw. Further, there is clinical evidence that actinomycosis has followed the extraction of a septic tooth. Thoracic actinomycosis has followed the accidental disappearance of a tooth down the trachea, and in one case the knuckles have become infected in a patient who had knocked out an opponent's tooth with his fist. The organism always grows in association with the Gram-negative *Bacillus actinomycetum comitans*.

Once introduced, the organism adheres to some point of the surface of the alimentary or respiratory passages, penetrates then to deeper parts, and forms local lesions in different parts of the body. These consist mainly of inflammatory changes, of more or less intensity, set up around the granules, so as to form slowly growing tumours, which ultimately suppurate, break down, and discharge. From the continued growth and multiplication of the parasite at one spot—as, for instance, in the liver—large tumours may be formed, three or more inches in diameter, consisting of a kind of cavernous tissue, the trabeculæ of which are fibroid, while the spaces contain pus, in which the yellow granular masses of fungus lie loose. A remarkable feature of the disease is the way in which lesions extend by contiguity from one tissue to the next over long periods of time; but occasionally the parasite is conveyed by the vessels to remote parts, and a more widespread deposit by *metastasis* occurs. It is characteristic that the lymphatic glands are rarely involved.

Symptoms and Course. These depend on the seat of the primary invasion.

In the superficial type a tumour is generally first noticed under the skin in the submaxillary, parotid or sterno-mastoid regions, and sometimes elsewhere on the surface of the body. It is hard, does not affect the skin, is chronic in its course, varies in size from time to time, and tends to spread, leaving for a time a narrow band of firm tissue in its track. Ultimately the skin becomes involved,

obscure fluctuation is felt, and a thin, sero-purulent, odourless fluid, containing the sulphur granules, is discharged. A sinus is formed, which rarely closes, but continues patent with slight secretion. In the cervico-facial region trismus is a characteristic symptom; the lesion may resemble an alveolar abscess (38). It may form in the substance of the lower jaw, and expand the bone. An extension to the base of the skull or the mediastinum by means of the pharynx is a possibility. Penetration of the *œsophagus* has led to mediastinal abscesses and erosion of the vertebræ.

In *intestinal actinomycosis*, which involves most frequently the cæcum or the appendix, the mucous membrane presents on its surface patches of whitish material, covered with yellow and brown granules. The patches are about two-fifths of an inch in diameter and one-fifth of an inch thick, and adhere firmly to the membrane. The disease may also cause swellings in the substance of the intestinal wall, from which it may perforate into the peritoneal cavity, or, by means of adhesions, invade adjacent viscera or the abdominal wall at almost any point. The *liver* is often secondarily infected in intestinal cases, and then contains large prominent masses, having the structure above described. Clinically

FIG. 7.—Sagittal section of a Liver showing the Lobulus Spigelii honeycombed by Actinomycosis.

such tumours may present the characteristics of hepatic abscesses, with local pain, tenderness, remitting fever and rigors.

When actinomycosis affects the *lungs* the symptoms may be bronchitic or pneumonic. In the former case there may be a close resemblance to putrid bronchitis, the sputum separating into two layers, the upper clear and the lower turbid, the latter containing the ray fungus. When the substance of the lung is affected, pneumonia occurs in patches, the patients cough and lose flesh, and the expectoration is either thick and muco-purulent, containing the typical granules, or it may be viscid, translucent, and rusty, like pneumonic sputa. There is often a close resemblance to phthisis, but the posterior and lateral portions of the lungs are involved, not the apices; and the sputum is, of course, free from tubercle bacilli. If the inflammatory lesions reach the surface, they set up pleurisy or pericarditis. Effusion takes place, or the lung becomes adherent to the chest wall, which then becomes involved, and ultimately soft diffused inflammatory swellings appear on the chest, which may fluctuate, break, and discharge purulent fluid containing the fungus. From the lung also the inflammatory track of the organism may stretch through the diaphragm into the abdomen, or behind the diaphragm to the psoas and iliacus muscles, or between the ribs to the surface of the chest. In a case of this kind recorded by Pringle, in which the skin was secondarily involved, there were large, soft, fleshy, sarcoma-like growths on the back of the chest, of mottled, purplish-red and yellow colour, covered by very thin skin, and presenting small ulcerative openings, from which a sticky fluid oozed, and in which lay a purulent fluid containing actinomyces granules. These processes are commonly very slow, and are accompanied with varying amounts of fever in different cases. A primary infection of the *skin* is

much rarer. The actinomyces is the cause of one of the white varieties of madura foot (see p. 1028). Infection by the *female genital tract* with extension to the ovaries and Fallopian tubes is also recorded, and actinomycotic cerebro-spinal meningitis is known (39).

Diagnosis. The diagnosis may be suggested by the presence of indurated lesions which are nearly painless and slowly progressive, while surrounding tissue presents to palpation a special "wooden" resistance. The disease can only be positively identified by finding the sulphur granules in the pus, or on the granulating surface of the sinuses, or in the sputum and urine. Some care is required in looking for them. A few drops of pus may be shaken up vigorously in half a test-tubeful of water, fitted with a cork, when the granules will be seen on holding the tube up to the light. One of these may be then placed on a slide and lightly crushed with a cover glass, when a low power will show the characteristic radiating structure. On crushing further the mycelial filaments may be seen; they are stained rather irregularly by Gram's method. Finally, anaerobic cultures of the organism should be made.

Prognosis. Death takes place from direct extension to vital structures, generalised pyæmia or by amyloid disease. There were nine recoveries out of ten cases in which the face or neck was affected, but the prognosis is bad in thoracic and abdominal cases (Colebrook).

Treatment. Surgical measures should be adopted in the first place if possible, multiple incisions being made into the tumours and the granulating surfaces being thoroughly cleaned by rubbing with dry gauze swabs, in preference to a sharp curette, which injures the surrounding healthy tissue. Potassium iodide has a powerful influence in the treatment of actinomycosis, and very remarkable results have been obtained under its use. It should be given to the extent of 2, 3, or 4 drachms daily, and better at short intervals of two or three hours during the twenty-four hours than in two or three doses or at longer intervals. Vaccines and arsenobenzol are other remedies which have been employed. Deep X-ray therapy is of value. As the organism is anaerobic oxygen by local injection or continuous inhalation might be tried.

Sporotrichosis. A number of different species of *Sporotrichum* have been described and their classification is by no means complete. *S. schencki* is one of the best known. In pus the parasites appear as oval bodies, 2 to 4 microns long by 1 to 3 microns broad, often situated within the large mononuclear leucocytes; after treatment with two or three drops of potassium hydroxide (20 per cent.) they appear microscopically as a tangled mass of fine, septate mycelia with oval spores on the ends of the filaments. *Sporotricha* may gain access to the tissues through the abraded skin from infected soil, pricks from the barberry shrub, biting insects or from the ingestion of contaminated food.

Symptoms. In localised *lymphangitic* sporotrichosis the primary lesion generally involves the hand and is the result of some infected abrasion of the epidermis or cutis. After a variable period of weeks to months a painless, cord-like thickening of the lymphatic vessels appears with multiple subcutaneous gummas along its course. General dissemination is rare. In the *cutaneous* type the onset is insidious and the local lesions generally painless. Months may elapse between the appearance of single, subcutaneous gummas or they may occur in crops or in rapid succession. Ulceration with the formation of cup-shaped ulcers may or may not result. Pyrexia and other manifestations of toxæmia are generally lacking. Where the *mucous membrane* of the upper alimentary tract is affected ulceration of the larynx may end fatally, while involvement of the intestinal mucosa may or may not lead to a diarrhœa accompanying blood and mucus in the stools.

Systemic involvement, whether associated with cutaneous, mucosal or osseous lesions, is generally characterised by fever of sudden onset, chills, rigors, digestive disturbances, secondary anæmia and loss of weight. A neutrophile leucocytosis

is marked, the total count varying from 15,000 to 30,000 cells per centimetre. *Leptomeningitis* is rare.

Diagnosis. The diagnosis depends on demonstrating the sporothricha in the pus or cerebro-spinal fluid or reproducing the disease in laboratory animals by inoculation. **Prognosis.** Early diagnosis and treatment is most important. Chronic cases with localised skin lesions generally recover, but those with systemic manifestations and severe fever, and cases with involvement of the pharynx and upper respiratory tract do badly. **Treatment.** Potassium iodide in increasing dosage to the limit of tolerance should be administered, and continued for at least six weeks after all signs of the disease have disappeared (Jacobson), while local abscesses should be aspirated and irrigated with Lugol's solution. X-rays may also be of assistance.

Blastomycosis. (*Chicago Disease : Gilchrist's Disease*). Males of the industrial classes are mainly affected though people of any age or either sex are susceptible. It may occur in any part of the world, but is specially prevalent in Chicago. Some observers hold there is only one *Blastomyces* which causes blastomycosis, other authorities state there are two, *B. immitis* and *B. dermatitides*. When blastomycotic pus is treated with a drop or two of 20 per cent. potassium hydroxide they appear microscopically as oval or round highly refractile bodies, measuring 5 to 20 microns in diameter and containing vacuoles and granules. Budding forms are frequently observed.

Symptoms. The clinical picture is very variable and any organ or tissue in the body may be involved. Primary cutaneous lesions may be subdivided into papulo-ulcerative, papillomatous and gummatous types which cause discomfort and pain locally, but no generalised features in the absence of systemic involvement. Secondary cutaneous lesions generally manifest themselves as ragged superficial ulcers with soft granulating bases covered by crusts which may heal spontaneously: deeper abscesses may also form leading to ulceration or the formation of fistulæ and sometimes they communicate with destructive lesions in the muscles and bones.

In systemic blastomycosis widespread visceral involvement occurs with chills, fever and a clinical picture resembling acute or sub-acute pyæmia. The mode of onset varies, sometimes being very sudden and acute, in other cases mild or insidious. The lungs are involved in 95 per cent. of cases with signs and symptoms of pleurisy and pneumonia, while renal involvement gives rise to nephritis or pyelonephritic features. Involvement of the central nervous system leads to meningitic symptoms, while blastomycotic osteomyelitis, periostitis and arthritis may ensue. Involvements of the tongue, larynx and mammary glands have been recorded.

Diagnosis. The diagnosis in either cutaneous or systemic blastomycosis is dependent on the demonstration of this budding yeast fungus in pus, pulmonary exudate or cerebro-spinal fluid. A marked leucocytosis varying from 15,000 to 40,000 cells per centimetre with an absolute and relative increase in the neutrophile granulocytes is characteristic. **Prognosis.** The course is variable and is generally benign in the localised, cutaneous varieties, but if improperly treated the condition may last with periods of remission and relapses for years. The systemic types are always of grave significance. **Treatment.** Local types of blastomycosis should, if feasible, be treated by total resection with the cautery or carbon dioxide snow and potassium iodide given internally to the point of tolerance. Local treatment with radium and X-rays when combined with iodides have in some cases yielded good results.

Systemic blastomycosis is always difficult to treat. Fresh air, adequate rest, and a nourishing dietary are important and iodides should be administered in full dosage in all cases. Tincture of iodine, minims v t.d.s., increasing by 1 minim per day up to the point of tolerance, is also advised. Vaccines of the blastomyces killed at 110° C. have been employed with promising results (60).

Torulosis. Age and race exert no influence on the incidence of the disease which, however, is more common in males than in females. The fungus (*Torula histolytica*) is a yeast-like organism which reproduces only by budding, produces neither mycelia nor ascospores, ferments none of the sugars, and has a predilection for the central nervous system and lungs (Jacobson). In sputum, pus, or cerebro-spinal fluid they appear as spherical or oval bodies 3 to 15 microns in diameter with an enveloping cell wall. The parasites may be mistaken for lymphocytes and for this reason it is always advisable to make cultures from cerebro-spinal fluid in suspected cases, examining the cultures for a period of at least ten days (Jacobson).

Symptoms. The incubation period is unknown. The manifestations may be local or systemic, the cerebro-spinal system and the lungs being most frequently involved. More rarely other organs such as the lungs, liver, spleen, kidneys, small intestine and mesenteric glands may be involved. There is a moderate leucocytosis and fever generally accompanies the systemic disease. (1) *Local torulosis*. This is a rare manifestation, but abscesses involving the spinous processes, pelvic bones, nasal septum and tongue have been described. (2) *Cerebro-spinal torulosis* is characterised by moderate fever, headache, visual disturbances, mental symptoms and paresis and paralysis of different kinds. The cerebro-spinal fluid is under increased pressure, contains globulin, an excess of leucocytes and *Torula histolytica*. (3) *Pulmonary torulosis* is a sub-acute or chronic disease with pulmonary manifestations and may be confused with tuberculosis, syphilis, neoplasm and other pulmonary mycoses; *Torula histolytica* may be found in the sputum.

Diagnosis. The diagnosis can only be made by demonstrating the infective agent. **Prognosis.** The course of the disease is essentially sub-acute or chronic, its duration varying from a few weeks to two years. In localised torulosis the prognosis is good if radical surgery be adopted, but cases with systemic involvement almost always die. **Treatment.** Resection of the local lesion preferably with the electric cautery is essential. No known treatment is successful, but Jacobson advises colloidal copper as worthy of trial.

Aspergillosis. Aspergillosis is largely an occupational disease and is common amongst those dealing with birds such as pigeons and parrots, handlers of grain, house cleaners and hair sorters who use rye flour to free the hair from grease. Most species of *Aspergillus* are entirely saprophytic. *A. fumigatus* is definitely pathogenic and has fulfilled Koch's postulates: it is found in quantity in soil and dust originating from agricultural products. A number of other species such as *A. repens*, *A. versicolor* etc., have been isolated from the external ears, skin lesions and sputa, but their claim to pathogenicity is not so clear. To demonstrate the organism which appears as a stalk or conidiophore with a spore-bearing head, pathological exudate such as sputum or pus should be mixed with a drop of 20 per cent. caustic soda to make a thin film. They grow readily on potato and bread and may be cultured on any laboratory medium. The condition was produced experimentally in animals (45).

Symptoms. Three groups have been described clinically with cutaneous, middle ear and pulmonary lesions. The status of cutaneous aspergillosis is very doubtful, and in the vast majority of cases aspergilli isolated from the skin are pure saprophytes. They probably contribute to inflammatory conditions and ulceration of the external auditory meatus (otomycosis). Examination reveals the lining membrane and tympanum to be covered with black, powdery granules or a greenish-white layer containing clumps of black granules. Pulmonary aspergillosis presents a variable clinical picture and may simulate acute bronchopneumonia, the patient being gravely ill, with identical signs and symptoms and X-ray picture. In the more chronic types hæmoptysis is common, and cough, loss of weight, blood-stained sputum, night sweats and an evening rise in temperature lead to the suspicion or diagnosis of tuberculosis; as a general rule,

however, these patients are well nourished and maintain a fair standard of health (Jacobson).

Diagnosis. The occupation of the patient, his well-nourished condition, and the absence of tubercle bacilli may lead to suspicion, but the diagnosis can only be definitely made by demonstrating *A. fumigatus* in the sputum by microscopic examination and cultural methods. **Prognosis.** Generally dermal and interstitial pulmonary aspergillosis run a chronic course lasting many months or even years, and the outlook is good, but the acute form terminates fatally—sometimes in a few weeks. **Treatment.** Local treatment for dermal lesions consists in the application of dressings with 1 per cent. copper sulphate solution combined with X-ray treatment or, if desirable, copper ointment. For the pulmonary type, potassium iodide to the point of toleration should be given combined with rest, liberal high vitamin diet and fresh air. Aspergillus vaccines have proved disappointing.

Spirochatal Disease

SYPHILIS

Syphilis, or The Pox, is a specific disease due to infection with an organism either through the skin or mucous membrane (acquired syphilis) or through the umbilical cord (congenital syphilis). The acquired form consists of a lesion at the seat of inoculation (*primary* lesion); lesions of the skin, mucous membranes, and other parts after an interval of a month or more (*secondary* lesions); and, after one or more years, deeper lesions of the skin, bones, muscles, viscera, central nervous system, and arteries (*tertiary* lesions). While the *primary* stage of syphilis means that the visible lesion is localised in the neighbourhood of the site of inoculation, the separation of the *secondary* from the *tertiary* stage is distinctly artificial, as both are due to essentially the same pathological process attacking different parts of the body after generalisation of the infection. However, the distinction is useful in the clinical description, and so it will be retained. Syphilis is also the cause of locomotor ataxy and general paralysis of the insane, two diseases of the central nervous system that are sometimes classified together under the term *parenchymatous syphilis*.

The micro-organism of syphilis is the *Treponema pallidum* or *Spirochæta pallida*, first described in 1905 by Schaudinn and Hoffman. It is a long thin filament, of spiral shape, with from six to fourteen coils, and tapering at the ends to a sharp point. The length is from 4μ to 20μ , the breadth about 0.27μ , and it is stained a rose-pink with Giemsa's stain. It has been found at the seat of infection before there is any evidence of a sore, in chancres, in the lymphatic glands associated with them, in the skin papules of primary and secondary syphilis, in mucous patches and condylomas, and in the blood and spleen. In the gumma of tertiary syphilis, the spirochætes often occupy the peripheral parts. In congenital syphilis, the organisms are found in great numbers in the blood, and in the internal organs, viz. the liver, spleen, lungs, and suprarenal bodies. Noguchi and others have found spirochætes in the cortex of the brain of general paralytics; they have also been demonstrated in the walls of the aorta in syphilitic aortitis (see Fig. 99, p. 1035).

ACQUIRED SYPHILIS

Infection. Syphilis is, as a rule, communicated during sexual intercourse, the delicate epithelium of the mucous membranes brought into contact allowing of the easy transmission of the virus. Cracks or abrasions of the mucous membrane do not seem to be necessary for the reception of the virus, though they must undoubtedly favour it. Inoculation by sexual intercourse takes place commonly in the *male* on the glans penis, prepuce, in the sulcus behind the glans or on the side of the frenum, and occasionally on the scrotum or in the pubic

area, or at the urinary meatus. In the *female* inoculation most commonly occurs on the labia, the fourchette, clitoris and the urinary meatus, and occasionally on the cervix uteri, but rarely on the vaginal wall. Syphilis may also be transmitted in other ways—for instance, in the act of kissing, by smoking pipes previously used by syphilitic persons, or by contact of syphilitic sores or secretions with the abraded finger of the medical man. After inoculation there is usually a period of *incubation*, varying from three to five weeks; the extreme limits are from ten days to three months.

Primary Lesion. The first sign is a small red itching papule, which gradually enlarges in all directions like a flat button; the surface is dry, or scaly, or superficially ulcerated and covered with a crust of dry secretion. The surrounding tissue becomes indurated in a week or ten days from the first appearance of the papule; and the lesion is known as the *hard, indurated, or Hunterian chancre*. On the mucous membrane the lesion may be scarcely so well marked; it begins as a vesicle with a red base; the vesicle breaks, and forms a shallow ulcer, the floor of which becomes indurated. In the course of time, and it may be some months, the induration gradually disappears, the ulcer heals, and a patch of pigment is left behind for a while. In a very early stage of the infection—even before the appearance of the primary sore—the spirochætes are transmitted to the *glands* of the groin; and from seven to fourteen days after the appearance of the hard chancre a single large indurated gland, the *primary bubo*, may be felt, with occasional small shotty glands beside it. These remain freely movable upon one another, without adhesion to or reddening of the skin, and they do not suppurate.

Extragenital sores mostly occur on the lips, finger, face, breast, tongue, or eyelid. They are usually larger than genital chancres, and the associated glands are always large and hard. On the lip or tongue ulceration begins early, and the base is often covered with a thick pseudo-diphtheritic membrane.

Secondary Lesions. The appearance of these lesions from five to eight weeks after the appearance of the primary sore indicates the generalisation of the infection throughout the body. Such lesions may continue to appear at any time up to twelve months or more. The most constant are certain eruptions on the skin (*syphilodermia, syphilide*), faucial inflammation, and enlargement or induration of lymphatic glands; others are febrile reaction, anæmia, pains in the temples, back, or limbs, swelling of the joints, iritis, and falling of the hair. Albuminuria may occur.

Eruptions. There are four main characteristics in secondary syphilitic skin eruptions:—

1. Lesions of different types are present together (*polymorphism*), but the size of the spots does not vary much. Large diffuse lesions are not seen.

2. The eruption is widely spread and copious.

3. Itching is uncommon; but this feature is not constant, and there may be concomitant lesions, such as scabies or pediculosis.

4. The shape of the lesions tends to be round, and the spots may be grouped or in rings. Except in the case of the macular eruption, the colour resembles raw ham.

The different types of secondary lesion and their differential diagnosis are as follows:—

1. The *macular syphilide*, or *roseola*, which forms rose-coloured round or oval spots about the size of a threepenny bit, rather thickly grouped. The trunk, neck, limbs, palms and soles are affected. There is no infiltration or scaling. It lasts from three weeks to two months, and may recur. It does not itch. It must be distinguished from measles and rubella and *pityriasis rosea*. The latter consists of pink spots of varying size covered with fine scales, and there is frequently a history of a “herald” spot, seen first of all, which is of larger size than the other lesions, and the patient often complains of itching.

2. A *follicular syphilide*, consisting of small dull red papular elevations, with

a hair in the centre of each ; they are often capped with a dry scale, and sometimes become pustular. They must be distinguished from *acne vulgaris*, which usually has a long history.

3. The *papular* syphilide consists of hard elevations, flat or hemispherical, or more prominent still, so as to form nodules or tubercles, which come out in crops irregularly over the whole body, like the macular syphilide, or grouped in clusters; the papules are red or ham-coloured, and have a shiny surface, often with a ring of fine scales round the edge ; they may occur on the rose spots of the macular syphilide. This variety must be distinguished from *lichen planus*, where the lesions are polygonal, flat-topped and shiny, with lilac or violet tint, and usually itch. In half the cases of lichen planus there are white papules, streaks or patches in the mouth ; but there is no ulceration of the fauces or enlargement of the lymphatic glands, as in syphilis.

4. The *squamous* syphilide consists of infiltrated coppery or ham-coloured papules capped with scales, and is common in the flexures. It must be distinguished from *psoriasis*, where the lesion is not infiltrated, and the scales are of a bright silvery type. Further, psoriasis occurs particularly on the extensor surfaces of the knees and elbows. *Seborrhæic* lesions must also be distinguished. These consist of round spots or circinate lesions with greasy scales ; the scalp and margin of the forehead are commonly affected, and they also occur particularly in the middle line over the sternum, between the scapulæ and in the sub-mammary regions. Itching is common.

5. *Rupia* is a comparatively rare lesion, occurring in debilitated subjects. It consists of a round or oval ulcer with a purplish edge and soft base, exuding blood-stained pus, which dries to form a characteristic limpet-shell crust. On healing it forms a deep scar. It must be distinguished from neglected patches of *psoriasis* which are covered with masses of brown scales. In the latter case on removing the scale a number of bleeding points are seen, but no ulcer, as in rupia.

Other forms are—(6) *syphilitic keratoderma*, in which there is thickening of the horny layer of the epidermis of the palms and soles, which may be mistaken for chronic eczema or psoriasis.

7. *Syphilitic alopecia*, which may take the form of general thinning or small patches of baldness about the size of a sixpence. The latter must be distinguished from *alopecia areata*, where the bald areas are round or ovoid and quite smooth, with club-shaped hairs at the spreading edge.

8. The *pigmentary syphilide* on the sides of the neck, consisting of an ill-defined area studded with white spots, occurring almost exclusively in women during the first two years of the disease. Arsenical pigmentation resembles it closely ; but the latter is found on covered parts, *i.e.* on the trunk.

9. *Mucous patches* are moist papules and *condylomas* are broad warty vegetations, which occur commonly about the genitals, perineum, and anus, in the axillæ, groins, and under the breasts, and at the angles of the mouth—in any place, indeed, where the skin is thin and constantly moist. These lesions are extremely infectious. They are often rather extensive, with well-defined edge, moist surface, and dirty grey secretion. They are to be distinguished from venereal warts, described among the diseases of the skin.

Sore Throat. Coincidentally with the rash, or even before it, the throat becomes affected ; there is a diffused redness of the fauces, with enlargement and excoriation of the follicles ; but the most characteristic feature is the swelling and symmetrical ulceration of the tonsils. The ulcers are often kidney-shaped, superficial, with grey borders, painless, and not of very long duration. Sometimes, however, the tonsillar ulcers are much more persistent, extend to the soft palate and uvula, have bright red edges, and are covered with a yellowish-grey secretion, the removal of which is followed by bleeding. Other changes in the mouth in the secondary stage are white spots, like those produced by the application of nitrate of silver, mucous patches on the tongue, or faucial pillars or inside

the cheeks, bald patches on the tongue from the destruction of the papillæ, or enlargement of the tongue, which is of bright red colour, with hypertrophied papillæ, or irregular prominences and deep sulci between them; this last condition is aggravated, or in part caused, by excessive smoking. The lesions in the mouth must be distinguished from aphthæ, which are rounded yellow, painful superficial lesions, from herpes, which is also painful, and occasionally from erythema multiforme with extensive lesions in the mouth. The lesions on the fauces must be distinguished from Vincent's angina.

The *lymphatic glands* are enlarged, especially in the groins, above the inner condyles of the humerus, and at the back of the neck. The *fever* of secondary syphilis is often entirely absent, or it is represented by no more than a slight malaise or indisposition preceding or during the outbreak on the skin. In a small number of cases there is very distinct intermittent or remittent *pyrexia*, the temperature highest in the evening; and it may last for some weeks. The *periostitis* of secondary syphilis is slight; pains and tenderness are felt in the tibiæ, skull bones or clavicles, but they are of short duration, and nodes do not generally form, as in the tertiary stage. The *joints* are not often affected; but there may be synovial effusion, which is sometimes excessive (hydrarthrosis), and is liable to vary from time to time in the same joint.

The most common affection of the eye is *iritis*; it usually affects one eye before the other; the symptoms are photophobia and pain, with ciliary congestion, irregular pupil, obscured iris, and, in severer cases, nodules of rust-coloured lymph and blocking of the pupils. Iritis occurs from three to six months after contagion; at a later period still, but within the limits of secondary symptoms, there may be diffuse retinitis or choroiditis.

Various nervous affections, especially paralysis of cranial nerves and myelitis, are apt to occur within a few months or a year of infection, and thus fall within the category of secondary results. Such disorders show a considerable proportion of recoveries under antisiphilitic treatment.

Some other lesions occur at a time which is intermediate between the second and tertiary periods, such as scaly or peeling patches on the palms of the hands (*psoriasis palmaris*); enlargement of the testis with perhaps nodular deposit in the epididymis; choroiditis and retinitis; and transitory visceral changes not due to gumma—for instance, enlargement or tenderness of the liver and spleen, with failure in the blood-making process, slight and temporary albuminuria, and symptoms of impending pulmonary mischief. And, indeed, no hard-and-fast line can be drawn between the end of the secondary and the beginning of the tertiary stage.

Tertiary or Late Lesions. These are first observed from one to two years after contagion, and may recur at intervals for ten or fifteen years, or more. They are certain eruptions on the skin, periostitis and nodes on the bones, and lumps in the subcutaneous tissue, muscles, meninges, liver, spleen, testis, and other viscera.

Late Syphilides. The skin rashes of the tertiary period are variable, and may consist of maculæ or scaly patches. But the most characteristic is a dusky red, infiltrated patch, forming a circle or broad band curved in a half-circle or horse-shoe; part of the surface is covered with a brown or greenish scab, beneath which are deep ulcers with sharply cut edges. The lesion spreads in serpiginous lines, being made up of small gummas of the skin set in circles or segments of circles, which in turn ulcerate, while the old ulcers heal and leave scars surrounded by deeply pigmented skin. Sometimes such nodules will subside and leave scars even without ulceration, and altogether there is a general resemblance to lupus. Ultimately large, irregular patches, of several inches in diameter, may form, and they are frequent on the knee, thigh, shoulder, forearm, face, and neck. Sometimes much deeper infiltrations of the subcutaneous tissues occur.

Gummas. The lesion in the viscera and other parts which is so characteristic

of the later stages of syphilis is known as a *gumma*. This is a mass of granulation tissue which may very closely resemble tuberculous granulation tissue ; but giant cells are not so commonly seen, and the smaller arteries often show *endarteritis*. In the early stages it is grey, gelatinous and transparent ; but the cells undergo fatty changes, and caseation takes place, so that the centre becomes yellow, and the circumference develops into fibrous tissue, which contracts like that of a scar. Sometimes gummas break down completely, and suppuration, with destruction of the tissue in which they are situated, takes place ; thus caries and necrosis not infrequently follow nodes on the bones. In the liver gummas form large, more or less uniform, yellow nodules ; or a yellow caseous mass lies in the centre of a fibrous cicatrix ; or nothing is left but the fibrous cicatrix, with consequent depression and puckering of the organ. In the testis gummas also occur ; but this organ is often enlarged by a diffuse gummatous infiltration of its substance generally, and may afterwards atrophy from the formation of a dense fibrous tissue without any local nodular growth. For the clinical results of these lesions the reader is referred to the diseases of different organs. It will be sufficient here to say that gummatous periostitis, or nodes, occur especially along the anterior surface of the tibia, on the frontal and parietal bones, and on the clavicles. The patient suffers from pains, which are worse at night, and there may be found on the affected part flat, round prominences, from $\frac{1}{2}$ inch to 1 inch in diameter, soft, or even fluctuating, and very tender. This is not necessarily a sign of pus being present, as quite distinctly fluctuating nodes may entirely disappear under treatment. Gummas are sometimes found involving the synovial or perisynovial tissues of joints. A very definite *pyrexia* with the temperature rising to 101° or 102° in the evening, and falling to 98° or 99° in the morning, may accompany a gumma apart from suppuration. Syphilis attacks arteries, producing in the case of the larger vessels *arteritis* and *atheroma*, which may lead on to aneurysm, and in the case of the smaller ones syphilitic *endarteritis* (arteritis obliterans), leading on to myocarditis. There is a consensus of opinion that the cardio-vascular system is more commonly attacked than formerly. Several disorders of the nervous system are referable to syphilis ; some, like hemiplegia, are due to syphilitic endarteritis, leading to thrombosis and consequent softening of the nervous tissue ; when this occurs in the brain, it gives rise to hemiplegia, or in the spinal cord to acute or chronic paraplegia, including Erb's *syphilitic spastic paraplegia* ; another is probably a true infective myelitis ; others, like localised paralyses and convulsions, are due to gummas or meningeal thickenings on the surface of the brain and the roots of nerves. The mucous membranes are affected with deep-seated destructive ulcerations, such as are seen in the mouth, destroying the uvula and soft palate, with adhesion of the remainder to the pharynx, or in the trachea, bronchus or rectum, leading to stricture or stenosis of these passages. Late syphilis is also one of the causes of the lardaceous degeneration, even without the existence of any suppuration.

Parenchymatous Neurosyphilis. The latest results of this disease are certain pathological conditions, with accompanying symptoms, the association of which with syphilis was first determined by statistical evidence. These affections are tabes dorsalis and general paralysis of the insane, in which it is found that a history of syphilis is obtained in 70 to 80 per cent. of cases ; while some forms of ophthalmoplegia, optic atrophy, loss of pupil light reflex, show similar relations. This view is supported by the results of investigation of such cases by the Wassermann test, which is positive in the blood-serum in nearly 100 per cent. of cases of general paralysis and somewhat less in tabes, and by the discovery of spirochaetes in the brains of general paralytics. These diseases are much less amenable to treatment than other forms of syphilis.

Course and Termination. In all stages of syphilis there is a tendency for lesions to appear at sites of injury. As examples may be cited the mucous patches and glossitis of smokers, squamous syphilides on the palms of manual workers,

the gummatous bursitis affecting the pre-patellar bursæ of charwomen, and gumma of the frontal bone in Mohammedans, arising from the practice of striking the forehead during religious worship. Thorough treatment in the early stages may entirely prevent the occurrence of late symptoms, and the secondary symptoms may be avoided or rendered extremely mild by diligent treatment when the primary lesion is first recognised. The disease has no fatal tendency in the first two stages, but in late syphilis the gumma may act like other tumours, and cause death by direct interference with function, especially in the brain and meninges. Death also results from syphilitic disease of the arteries, from bronchial, tracheal, or rectal stenosis, from periostitis with necrosis of bone and pyæmia from lardaceous disease of the liver, spleen and kidneys, and from the disorders classed as parenchymatous syphilis.

Diagnosis. In the *primary* stage it is important to make the diagnosis as soon as possible, so that treatment may be carried out before generalisation of the infection has occurred. The chancre is distinguished by its induration, and by the presence of the hard primary bubo from: (1) *soft sore*, which is usually multiple and causes soft and tender enlargement of the glands; (2) *herpes genitalis*, where the lesions are superficial; (3) very rarely *lichen planus*; (4) traumatic ulceration. In addition, when the lesion has been untreated spirochætæ should be looked for. Some serum is obtained from the lesion or from the neighbouring gland and is mixed on a slide with a few drops of normal saline. The slide is examined with a $\frac{1}{2}$ -inch oil immersion objective by the dark-ground illumination. The spirochætæ, which appear white, are seen moving in the field.

From a medical point of view it is the recognition of the late syphilitic lesions that is most frequently required, and help is commonly sought in the former history of the patient. The points likely to be remembered are the occurrence of a definite sore other than mere gonorrhœa, the rash, the sore throat and the falling of the hair. Whether the sore was of the hard or soft variety may be unknown to the patient. The patient may be able to give consistent accounts of the rash, or of the ulcerated sore throat. In married women some reliance is placed upon the previous occurrence of still-births and deaths in infancy, and of eye troubles, etc., in the older children.

Search should be made for scars of the original sores on the penis in men, for scars of tertiary lesions on the skin and in the throat, for nodes on the tibiæ and skull, for hardness or atrophy of the testes, and for evidences of lardaceous disease, in the size of the liver and spleen and in the existence of albuminuria.

The diagnosis is sometimes assisted or confirmed by therapeutic measures, when, for instance, a suspected lesion yields rapidly to the treatment mentioned below.

By serological methods it is now possible to detect in the blood serum a specific result of syphilitic infection. Bordet and Gengou showed that if any *antigen* (i.e. a substance that has the power of calling into existence *anti-bodies* on being injected into an animal) is mixed and incubated at 37° C. with serum containing such anti-bodies, the two combine together and at the same time fix *complement*, an enzyme normally present in the blood. This phenomenon has been applied to the diagnosis of syphilis, and is known as the *Wassermann reaction*. The antigen originally consisted of an extract of syphilitic liver, and this was added to serum taken from the patient to be investigated. If complement is fixed, the patient is to be regarded as syphilitic. This fixation is determined by means of a special hæmolysis test. If red cells from some animal, like a sheep, are injected into another animal, such as a rabbit, they behave as antigen, so that the corresponding anti-body, or hæmolysin, is formed. If the red cells and serum containing the hæmolysin are mixed, hæmolysis occurs so long as complement is present, but does not occur in the absence of complement. For the test the suspected serum believed to contain syphilitic anti-body is heated to destroy complement and then mixed with the extract of syphilitic liver, and with normal guinea-pig's serum

containing complement. These are kept for an hour at a temperature of 37° C. and the mixture of rabbit's serum containing hæmolysin (but deprived of complement by previous heating to 56° C.) and the washed sheep corpuscles is then added, and the whole mixture further submitted to 37° C. for two hours. If the serum in question contains anti-body of syphilis, the complement will be bound, or fixed, by it in the first incubation, and the hæmolysin in the rabbit's serum, not meeting with free complement in the second incubation, will not destroy the corpuscles—*i.e.* there will be no hæmolysis. This event is called, in regard to complement fixation and to the presence of syphilis, a *positive reaction*. If, on the other hand, the anti-body of syphilis is not present, the complement will not be bound in the first incubation; it will co-operate with the hæmolysin in the second incubation, and hæmolysis will take place. This is a *negative reaction*. By carrying out the whole process on quantitative lines it is possible to judge from the amount of hæmolysis that occurs the amount of syphilitic anti-body present in the patient's serum.

As a matter of fact, the reaction as carried out at the present day has been modified in one particular way. For some unexplained reason it has been found unnecessary to use a syphilitic liver to prepare the antigen. Certain other substances will do, and an extract of human heart mixed with cholesterin answers the purpose, so that this is always used now as antigen, because it is easier to obtain. These facts indicate that the original explanation of the Wassermann reaction no longer holds good.

The Wassermann test gives a positive reaction in primary cases in from five to eight weeks after infection, in 95 per cent. of secondary cases, in 75 per cent. of tertiary cases, and in 50 per cent. of cases where syphilis is latent (D'Arcy Power). It is very frequently found (70 per cent. or more) in the case of apparently healthy mothers of children congenitally syphilitic. The child itself may give a negative reaction in spite of the mother's positive result, or a positive reaction may appear with the outbreak of definite symptoms. Conditions other than syphilis that give a positive Wassermann reaction are rarely met with in practice.

The Kahn reaction is another serum reaction which is used extensively in diagnosing syphilis. It depends on the fact that serum from a syphilitic patient can flocculate a saline suspension of a mixture of alcoholic heart extract and cholesterin.

In patients under treatment the reaction may become negative, and yet in many cases, if a small dose of salvarsan (*see below*) is injected, the reaction again becomes positive, showing that the syphilitic infection is still present; and freedom cannot be pronounced until the negative reaction persists in spite of this so-called "provocative injection" of salvarsan.

Prevention. As syphilis is rarely conveyed otherwise than by direct contact it should be easy to prevent its spread, if those who are known to be infected could be made to abstain from contact, sexual or otherwise, with healthy persons; but those who are infected do not always know that they are so.

Legislation has many difficulties to contend with. Following the report of the Royal Commission in 1916, the State has made grants of money for the purpose of providing means of bacterial diagnosis, of promoting the establishment of treatment centres all over the country free to all who apply, of educating practitioners in the use of newer methods of treatment, and of supplying salvarsan or its substitutes free to medical practitioners. In the vast majority of cases which have been exposed to infection, immediate disinfection—thoroughly washing the parts and rubbing in the 30 per cent. calomel ointment mentioned on p. 114—will prevent the primary sore; but in spite of this there may be generalised infection, so that observation by blood tests is necessary after disinfection. A solution of mercury cyanide (1 in 1,000) is an even better antiseptic.

Pregnant women known to be syphilitic, or demonstrated to be so by the

Wassermann test, should be promptly treated, to secure the health of the offspring.

The following facts may guide the medical man in advising patients. Both primary and secondary lesions are contagious, and the blood during these periods contains the virus. During the latent and tertiary stages the infectivity usually becomes progressively less but the disease may be transmitted many years after acquisition. It will be seen that syphilis of the foetus is probably always due to maternal infection (*see p. 115*).

As a rule, syphilis confers upon the sufferer immunity from fresh infection, though by some it is stated that the immune person is only an *uncured* syphilitic. Instances are recorded in which, after a long interval, a fresh primary sore and fresh secondaries have appeared, and here we must suppose that the protective influence, if it ever existed apart from the spirochæte and its toxins, has died out, as it does rarely in the exanthems.

Treatment. The extraordinary tenacity of the spirochæte of syphilis and its possible influence for years after infection upon the bodily structures makes it essential that treatment should be prompt and persistent over a long period of time. The following have a pronounced effect upon the disease: (1) mercury and its compounds; (2) certain arsenical compounds; (3) bismuth, which all act by destroying the spirochæte; (4) potassium iodide, which stimulates a tissue reaction, to absorb exudates.

(1) Mercury can be given in a variety of ways. For *intramuscular injections* a soluble preparation may be used such as the perchloride, $\frac{1}{10}$ to $\frac{1}{8}$ grain, dissolved in 0.9 per cent. salt solution, every day or every other day, or an insoluble one such as mercury in fine subdivision, calomel, or the salicylate suspended in a fatty medium of which there are a number of formulæ. The method of *inunction* with mercurial ointment is undoubtedly a very thorough way of introducing mercury into the system, but it requires to be done by expert attendants, and in view of other methods of treatment is rarely used now, except in cases of congenital syphilis in infants. *Oral* administration of mercury, the simplest method, is commonly used. The more usual preparations are the perchloride in doses of $\frac{1}{16}$ to $\frac{1}{12}$ grain (60 to 80 minims of the liquor) three or four times a day, and hydrargyrum cum creta (grey powder) in doses of 1 or 2 grains with the same frequency. Hutchinson advised 1 grain of grey powder with 1 grain of Dover's powder, if necessary, to be given every six, four, three, or two hours. During the use of mercury the patient should abstain from smoking and from stimulants, frequently clean the teeth and mouth, and live in every way as healthy a life as possible. Excessive treatment causes salivation (*see also Chronic Mercurial Poisoning*). Mercury has a very mild spirochæticidal action, but it acts persistently.

(2) Salvarsan was introduced by Ehrlich (1909), and was known later as arsenobenzol. As its method of administration is complicated, it is no longer included in the British Pharmacopæia; but the names may be conveniently used for this group of compounds.

Neo-salvarsan, or "914," is an allied drug, also known as novarsenobenzol, novarsenobillon, neokharsivan, novarsan, nearsphenamine (the official name). It is soluble in water, and so can be injected directly into a vein by means of a needle and syringe. The solution must not be kept, but must be injected immediately it is made. It must not be allowed to run outside the vein, as it is irritating; to avoid this a little blood is first sucked into the syringe so as to be sure the needle is properly in the vein, before pushing the plunger home. The injection should not be made on a full stomach and it is often advisable to give glucose beforehand.

Sulfarsenol, closely allied to "914," can be given intramuscularly or just over the gluteal fascia without undue discomfort, and is of value when the Wassermann reaction continues to be positive. It can be given without reference to

meals. Kharsulphan, metarsenobillon, sulphostab and myosalvarsan are all chemically like sulfarsenol and have all been devised for intramuscular injection. Silver salvarsan is a combination of sodium salvarsan with silver and has been found very useful in neuro-syphilis.

Arsenic preparations act rapidly in destroying the spirochæte; but not thoroughly. In fact, it is suggested that a strain of arsenic resistant spirochætes is being produced from insufficient treatment.

(3) Bismuth was introduced into the treatment of syphilis by Sézary and Levaditi after numerous animal experiments had shown that it has a powerful curative effect. It has a stronger spirochæticidal effect than mercury and is persistent in its action, differing in this way from the arsenic compounds. The majority opinion to-day places it in therapeutic power between the salvarsan preparations and the mercurial. It is always administered by injection, intramuscularly, or over the fascia covering the glutei. The preparations for intramuscular injection are very numerous. They may be divided into the soluble and the insoluble. An example of the soluble is a preparation of iodo-bismuthate of quinine (Solubyl), used by Fournier, when a quick effect is desired. The disadvantage of the soluble preparations is that, like the preparations used for intravenous injection, they quickly provoke the general signs of poisoning mentioned below. The insoluble preparations, such as the insoluble basic tartrate, the oxychloride, salicylate, or the metal itself in fine subdivision, are suspended in an oily or in a watery medium such as glucose solution, and of these probably the watery medium is better, as it is absorbed more evenly. For the same reason probably a compound is preferable to the metal in fine subdivision. Usually intramuscular injections cause little or no discomfort, and in this respect they have a great advantage over mercury. Treatment by bismuth alone is used for elderly patients, and in cases of intolerance to salvarsan preparations. The signs of bismuth poisoning are somewhat similar to those of poisoning by mercury. The more common are aphthous stomatitis, which is usually preceded by the formation of a slaty-blue line on the margins of the gums, albuminuria, colitis, vague aching in the back and limbs, insomnia, general depression and occasionally skin rashes rather similar to those provoked by arsenobenzol preparations.

(4) *Iodide of potassium* is especially useful in the treatment of later manifestations, but in other stages it may be used in combination with the perchloride of mercury. Under its use the most serious and alarming nervous symptoms, due to syphilitic gummatous lesions, rapidly subside, ulcerating skin lesions quickly heal, pains in the bones subside, and periosteal nodes disappear. Five or 7 grains three times a day are often sufficient, but in serious cases it should be pushed to $\frac{1}{2}$ -drachm or drachm doses three times daily; or as much as 20 grains may be given in a little milk every two hours through the whole day and night. The advantage of this, no doubt, lies in the thorough saturation of the system; otherwise, as the salt passes away rapidly by the kidneys, the amount in the body may fall very low in a long night interval. If iodide, in any dose, causes coryza, it should be taken much diluted—*e.g.* in half a tumblerful of water; arsenic may be added if it causes eruptions (*see* Medicinal Eruptions). General tonics, good food and sea air are desirable if it causes much depression, or the iodide of sodium may be given instead in corresponding doses, or a mixture of the iodides of potassium, sodium and ammonium in equal parts. If these fail, recourse may be had to mercury, either alone or with a tolerable dose of potassium iodide.

It is now generally recognised that a prolonged course of treatment is desirable, and this depends on the stage of the disease and the Wassermann reaction. In Harrison's table (33) the dose of the salvarsan preparation is stated in grammes of "914" or of Stabilarsan. An equivalent dose of silver salvarsan would be one-third. All these preparations are given intravenously. The dosage of the preparations which can be given intramuscularly, such as sulfarsenol, etc., is the same as that of "914." Hg means an insoluble preparation of mercury given

intramuscularly, and the dosage below is that of mercury in fine subdivision. If calomel is used the dosage is usually three-quarters of that stated in the table, and that of the salicylate is 50 per cent. greater. Bi means a good preparation of bismuth, preferably an insoluble compound, such as the oxychloride or the salicylate suspended in a glucose solution and injected intramuscularly or over the gluteal fascia. Mercury and bismuth are alternatives, and either (preferably bismuth) is administered at the same time as the arsenobenzol. The dosage in the tables is that recommended for males of average build and weight without clinical manifestations of disease of the central nervous system or of any viscus. For women the dosage is lower, according to weight.

A. PRIMARY CASES WITH NEGATIVE SERUM REACTIONS

Day of Treatment.	Neoarsphenamine, gram.	Hg with grain.	Bi or with grain.
1st	0.45	—	—
8th	0.45	i	iii
15th	0.45	i	iii
29th	0.60	i	iii
36th	0.60	i	iii
50th	0.75	i	iii
57th	0.75	i	iii
78th	0.75	i	iii
85th	0.75	i	iii
92nd	0.75	i	iii

Potassium iodide is given from the 58th to 77th days, and from the 127th to 147th day in a dosage increasing in each period from 15 to 30 grains a day.

A blood test is taken on the 92nd day. Whatever the reaction, a second course similar to the above is commenced on the 148th day. After this the patient is put under observation for two years, testing the blood serum every three months in the first year and every six months in the second. The tests at the end of the first and of the second years respectively are preceded a week previously by a provocative injection of 0.3 gram "914." If at all practicable, the cerebrospinal fluid is examined at the end of the first and second years.

B. PRIMARY WITH POSITIVE SERUM REACTIONS

- (1) As for sero-negative primary, followed by
- (2) No treatment for ten weeks.
- (3) Potassium iodide for three weeks.
- (4) A course of five injections as from the 29th to 78th days, but with only two weeks between the 3rd and 4th injections.
- (5) Assuming that the blood was negative on the 92nd day and at the end of each subsequent course, suspend treatment and observe as above. If not negative on the 92nd day or at any time later, proceed as for secondary cases.

C. CASES WITH CLINICAL SIGNS OF SECONDARY SYPHILIS

- (1) As for sero-positive primary, followed by
- (2) A repetition of the procedure shown in B (2) to (5).

D. TERTIARY AND LATENT

- (1) A course of 7 injections as from the 1st to 57th day in A.
- (2) Potassium iodide for three weeks.
- (3) No treatment for ten weeks.
- (4) Course of 5 as in B (4).
- (5) Potassium iodide for three weeks.
- (6) Repeat (1) to (5) twice.
- (7) No treatment for sixteen weeks.
- (8) Repeat (4) and (5).
- (9) No treatment for eighteen weeks.
- (10) Repeat (4).

This series of courses lasts over two years, and even then the serum reactions may still be positive. The question of persistence with treatment is debated. Harrison advocates keeping the patient under treatment with intervals of rest so long as the reactions are positive, believing that this is the best preventive of late effects. Others would not treat these "Wassermann-fast" cases for so long. Recently there has grown up the practice of combining the injection treatment of such cases and even earlier ones with the artificial induction of malarial fever. This arises from the good results obtained by such treatment in general paralysis. Finger advocates 3 grams of "914" in doses of 0.3 to 0.45 at five-day intervals followed by malarial inoculation and ten paroxysms of fever, which is then stopped by quinine, and on the day of the last paroxysm another course of ten injections of "914" is commenced. By this method the serum reactions are said to be converted to negative in a much higher percentage of cases than by purely drug treatment given in a very much higher total dosage. A milder procedure than the malarial treatment is to provoke a series of rises of temperature by injections of such foreign substances as anti-typhoid vaccine, milk and turpentine.

The treatment of syphilitic myocarditis and aneurysm (*see* p. 279), of hepatic syphilis (*see* p. 398), of syphilitic myelitis (*see* p. 666), and neuro-syphilis (*see* p. 681), are dealt with in the appropriate places.

The only contra-indications to treatment along these lines are intolerance on the part of the patient. Intolerance to arsenobenzol is fully discussed on p. 117, and it is essential to take the precautions mentioned there, since many deaths from poisoning have been reported.

The destruction of the primary sore will not prevent generalised infection, but, in view of the presence of organisms therein, it is advocated by some as an additional measure. Excision, cauterisation, and the application of an ointment—calomel 33 parts, lanoline 67, and vaseline 10—have been tried. Infiltration of the area with hectine, "914," or similar preparations, is probably more effective than applications.

CONGENITAL SYPHILIS

Children born of parents suffering from syphilis in any stage may themselves be infected with the disease. This transmission is less frequent in the tertiary stage. Congenital syphilis is due to infection of the foetus by the mother, who may herself have been the subject of syphilis before conception or may contract the disease during pregnancy. Foetal infection may occur through the placenta at any time during the pregnancy, and the later it occurs the better chance there is of the foetus surviving. Infection may occur during parturition. In this case a primary chancre develops at the site of an abrasion (*e.g.* from forceps), as the result of infection from primary or secondary lesions in the maternal passages.

It was formerly stated that a child might be infected with congenital syphilis

from the father, the mother being healthy. Further, under these circumstances, the syphilitic infant might infect a wet-nurse—e.g. causing a chancre on the nipple—but would not infect its own mother, thereby showing that the mother was in some way protected against infection, though she might manifest no lesions whatever. This is called *Colles' law*. The now generally accepted explanation is that the father has really infected the mother, who however shows no signs of the disease, and she passes on the infection to the foetus, and this is proved by the fact that the Wassermann reaction has been found to be positive in 95 per cent. of mothers of syphilitic children when they have been examined soon after the birth of the child.

Infection *in utero* does not always occur when there is maternal syphilis, and sometimes its transmission is irregular, as is shown by the fact that the same parents may have children showing a positive Wassermann reaction alternately with children showing a negative reaction, and one child may be badly affected, another not at all.

Death of the Foetus. One effect of syphilis in the parent is the early death of the foetus, with resulting miscarriage or premature birth. In fact, 15–20 per cent. of all miscarriages and still-births are due to syphilis. The fact of miscarriages having occurred in the history of a married woman may be important evidence as to syphilis in herself or her husband. It is not so easy to say the exact cause of the foetal death, whether from the immediate effects of the syphilitic virus or from some disease of the placenta. Hard yellow masses have been found in this structure, but usually there are no naked-eye characteristics. Microscopically the villi show increase in size and vascularity. Endarteritis is absent. On the other hand, the foetus not infrequently presents lesions of the bones, viscera, and skin which show that it may be profoundly diseased. In the bones there is irregularity and deepening of the line of calcification at the junction of the epiphysial cartilages and the shaft. This is described as osteochondritis or *epiphysitis*, and resembles the changes in rickets, except that in syphilis the calcification is more evident. The cartilage may be separated from the bone by soft granulation tissue or pus. The changes in the liver are described on p. 397. The lungs show increase in the interalveolar tissue, with compression of the alveoli and capillaries and sometimes gumma. Increase of connective tissue is present in the thyroid, thymus and pancreas, and ulcers in the intestines. Spirochætes may be found where the lesions are marked.

Early Symptoms. Epiphysitis, which occurs in about 16 per cent. of cases, is sometimes present in children born alive, the principal epiphyses being separated from their bones, and the limbs consequently lying useless, so as to give the appearance of paralysis. Occasionally also the child is born with a bullous eruption on the skin, or the rash comes out very soon after birth. The palms and the soles are always affected. This is a syphilitic rash, and must be distinguished from *Pemphigus neonatorum*, which is a bullous impetigo due to sepsis usually at the umbilicus. But in a large majority of cases the child is born not only alive, but healthy, fat, and plump, and remains so for three or four weeks after birth. Then it acquires a nasal catarrh, *rhinitis*, causing the symptom commonly known as *snuffles*, with a discharge, at first thin and serous, afterwards thicker, purulent, and drying up into crusts, which obstruct the nostrils, so that sucking is difficult. At the same time a *rash* appears, most commonly on the buttocks and adjacent parts of the thigh, back, and abdomen. It consists most often of circular patches, brownish red like the lean of ham, dry, shiny, and inelastic; the patches run together, and form larger areas of irregular shape, but mostly with a well-defined edge. This is to be distinguished from intertrigo, which occurs in the flexures, and from the “napkin rash,” a bright shiny red inflammation affecting the convex surfaces over the area which comes in contact with a dirty napkin (*see later*); and the two conditions probably sometimes co-exist. Less frequently the rash is papular, pustular, and bullous.

Other lesions occurring in early infancy are stomatitis, ulcerations about the lips and angles of the mouth, rapidly forming cutaneous abscesses, and periostitis; and the spleen is enlarged in very many cases. With all this the nutrition of the child may be little affected, but sometimes wasting results, and the face acquires a withered and shrunken appearance like that of an old man. In this stage death may occur; but under treatment, or otherwise, all the symptoms may subside, and the child may show no indications of the taint for many years, when, often about the time of puberty, symptoms appear which are more or less comparable with those of the third stage of the acquired disease. The Wassermann reaction is positive in 90 per cent. of the cases, and the mortality may be as much as 40 per cent.

Later Symptoms. These are—periostitis with the formation of nodes; synovitis, especially a chronic synovial effusion into both knees; scaly or lupoid skin eruptions, which are not very common; bilateral deafness coming on with noises in the ears, but without pain or discharge; disseminated choroiditis; dark brown punctate pigmentation of the *fundus oculi*; iritis; and keratitis. The last is common in inherited syphilis, not so in the acquired disease; it causes opacity of the cornea, which gradually increases till the cornea looks like ground glass. It is associated with ciliary congestion, and in late stages vessels may encroach upon the cornea, producing a "salmon patch." Its tendency is to recover. But, in addition to these fresh lesions, inherited syphilis may be recognised by some permanent deformities, the result mostly of those changes which took place in infancy. Such persons present a broad forehead, with unusual prominence of the two halves of the frontal bone; the bridge of the nose is broad and sunken; around the mouth are numerous linear cicatrices radiating from the orifice as a centre; and the permanent teeth, as was first pointed out by Hutchinson, show features from which alone an absolute diagnosis of the condition may be made. It is only the upper central incisors that can be relied upon for this purpose, though other teeth may be similarly affected: they are short, narrower at the edge than near the gum, and the edge presents a single central cleft or notch. This notch is at first, soon after the eruption of the tooth, filled by a notched edge of exposed dentine, which soon breaks away. This change in the teeth must be distinguished from the simple transverse marking, which may result from the excessive use of mercury in infancy, causing stomatitis, and interfering with the proper development of the tooth sacs. Periosteal changes in the tibia may result in a convexity of the anterior border, the so-called *sabre-shaped tibia*. Visceral changes are also not uncommon, such as enlargement of the spleen, cerebral inflammation or degeneration (see Cerebral Diplegia), occasionally orchitis, interstitial hepatitis (see Cirrhosis of the Liver), anæmia with or without splenic enlargement, and gummas revealing themselves in adult life.

Prevention. This may be considered under two heads:

(1) *Prevention of Infection of the Mother.* Men with syphilis should not marry until there is no danger of transmitting the disease. They should have had adequate antisyphilitic treatment and be free from all clinical evidence of the disease, and the blood should have given a negative Wassermann for at least three years. Sometimes the blood remains persistently positive. In such cases there can be no certainty, and the risk, though slight, must be explained to the patient. Not uncommonly a husband becomes infected from irregular sexual intercourse during the later months of pregnancy or the puerperium. Adequate and prompt treatment must be undertaken and he must abstain from sexual relations until free from infection.

(2) *Treatment of the Syphilitic Mother before and during Pregnancy.* The Wassermann reaction is of great value in diagnosing maternal syphilis, because many women suffer from syphilis without knowing it. The primary lesion may be hidden away and cause very little discomfort. Often there is additional

evidence of syphilis, *i.e.* a history of still-births, etc., or a positive Wassermann reaction obtained from the husband's blood, which should always be tested. Antisyphilitic treatment with arsenobenzol compounds and bismuth may be given throughout pregnancy, and should be continued afterwards.

Treatment. Mercury is rapidly effective in infantile syphilis. A grain of grey powder three times a day or liq. hydrarg. perchlor. 10 to 20 minims, will quickly disperse the rash, snuffles or other symptoms, and improve the nutrition. An excellent method is by mercurial ununction, $\frac{1}{4}$ drachm of ung. hydrargyri being rubbed into the abdomen daily. Calomel powder may be applied to mucous patches or ulcerations of the skin. Bismuth is even more effective but must be administered by intramuscular injection. While such treatment is usually effective in the treatment of symptoms, to effect the complete eradication of syphilis it is essential to administer neo-salvarsan compounds and bismuth over several years. Intramuscular injections of sulphostab may be given to an infant a few weeks old, increasing from an initial dose of 0.05 to 0.15 gram at two months of age. The toleration of salvarsan by infants is high. Bismuth preparations are also well tolerated and may be given by intramuscular injections of 0.25 c.c. of a 10 per cent. suspension of bismuth oxychloride at weekly intervals. Even with apparently satisfactory results the child should be kept under periodical clinical observation and repeated Wassermann reactions done until after puberty. Any clinical or serological relapse of syphilis will indicate further prolonged treatment.

POISONING BY ARSENOBENZOL

On account of a wide variation in the tolerance of patients to the intravenous and intramuscular injections of arsenobenzol compounds symptoms of poisoning are not uncommon. In the early years of the use of salvarsan, before this danger was recognised, there were many fatalities. The toxic symptoms may appear either at an early stage of treatment or they may be greatly delayed and bear no apparent relation to the injections.

Early Toxic Effects (1) *Vasomotor reaction.* This is a sudden syncope with rapid cyanosis and œdema of the face and extremities during or immediately after one of the first few intravenous injections. Although alarming the condition is rarely fatal and usually reacts promptly to the injection of adrenaline. Treatment may be resumed with intramuscular injections. (2) *Jarisch-Herxheimer Reaction.* This is a general reaction with malaise and fever and exacerbation of the existing syphilitic lesion, *e.g.* in the skin or meninges, and it is probably due to the stimulation of spirochaetes by a dose of drug insufficient to destroy them. It is usually seen after arsenobenzol preparations, but may be caused by mercury or bismuth. The phenomenon has been called *biotropism*, and similar exacerbations have been observed with streptococcal focal lesions and malaria. (3) Mild *gastro-intestinal* irritation with vomiting and diarrhœa, occasionally followed by transient jaundice, may occur from twelve to forty-eight hours after an injection, particularly in constipated patients. (4) *Cutaneous eruptions*, urticarial, erythematous and papular are not uncommon. Further treatment must be delayed and administered with caution. Purpura is rare but denotes a dangerous idiosyncrasy; it may be followed by severe or fatal aplastic anæmia. (5) *Encephalitis Hamorrhagica.* This serious condition is characterised by drowsiness with intense headaches for a few days, followed by epileptiform convulsions and rapidly deepening coma. The majority of the patients are young adults, and this condition, which follows the first two or three injections, is usually fatal.

Delayed Toxic Effects. (1) *Jaundice* of more prolonged duration may occur after one or more courses of treatment, and may be delayed until some months after treatment has ceased. There are no characteristic signs of the toxic

origin of the jaundice, and the differentiation from catarrhal jaundice is difficult. Pyrexia and pruritus are usually absent and the patient suffers little if at all from depression. Very rarely acute necrosis of the liver ensues with fatal result. (2) *Dermatitis*. Severe *exfoliative dermatitis* may occur after a series of injections, and is often preceded by transient erythema or urticaria. In the acute stage there is generalised erythema with œdema of the skin. Irritation is very marked. Vesicular formation and gradual exfoliation follow. Recovery is slow but septic infection may occur with fatal result from broncho-pneumonia and toxæmia. (3) *Neuritis*. Peripheral neuritis and optic neuritis are rare complications. The tolerance of infants and children for arsenobenzol preparations is excellent; toxic effects are rarely seen.

Prevention. At present all commercial samples of arsenobenzol and its derivatives are tested by the Medical Research Council so as to exclude impurities and to estimate toxicity. Patients must be carefully examined before treatment for signs of liver or kidney disease and must be watched during treatment for any signs of intolerance. In doubtful cases the hepatic efficiency may be determined (see p. 383), the levulose and van den Bergh tests being specially valuable. Urobilinogen in the urine is an early sign of hepatic insufficiency.

Treatment. Any sign of mild intolerance should warrant caution during further treatment. The doses must be reduced and the intervals between the injections lengthened. Sodium thiosulphate, 15 grains, t.d.s., is given for the milder toxic effects, and 0.6 to 0.9 grams intravenously daily for the more severe cases. Injections of calcium gluconate or calcium thiosulphate are of value in toxic hepatitis. No further arsenobenzol therapy should be given after a severe toxic reaction.

DISEASES OF THE ORGANS OF RESPIRATION

DX

18

Ce

EXAMINATION OF THE CHEST

a

Inspection. By looking at the chest in front, behind, and from above, abnormalities such as various skin eruptions, scars from old empyema operations or gunshot wounds, and enlarged veins may be noticed, and any alteration in its shape and movements can be detected. As regards enlargement of the veins, it is important to distinguish between those that are distended, which may suggest obstruction to the venæ cavæ internally, and those that happen to be more superficial than usual and are of no pathological significance. The chief points to be noticed in a healthy adult chest are as follows: It has a somewhat flat oval form—that is, the antero-posterior diameter is much less than the transverse; its greater breadth is at the lower part; the clavicles are only slightly prominent with but little depression above, and scarcely any below them; the position of the nipple is on the fourth rib, or on its upper or lower border; the angle (*epigastric angle*), which has its apex at the ensiform cartilage, and is bounded on each side by the seventh and eighth costal cartilages, is from 95 to 105 degrees; the scapula is closely adapted to the posterior part of the thorax; and the spine is straight. In inspiration the chest should expand from 2 to 3 inches in circumference, the two sides should move symmetrically, the epigastric angle should be widened, the sternum thrown forwards, and the lower ribs lifted; and there should be only very slight recession of the lowest intercostal spaces on deep breathing.

By inspection abnormalities in the shape of the chest are noted, and these may be due to the following causes: (a) Disease of the *lungs*. In emphysema the chest is more capacious and the epigastric angle wider than normal. In fibrosis of the lung, as in phthisis, the chest is asymmetrical, owing to local contraction, usually at one or other apex. (b) Disease of the *bones*, such as deformities due to rickets and angular and lateral curvatures of the spine. The chest may become asymmetrical, or still show bilateral symmetry although abnormal in shape. Bronchitis and broncho-pneumonia have usually played a part in producing the deformities due to rickets. (c) Hypertrophy of the *heart* in young subjects may lead to a local bulging of the chest wall on the left side.

The circumference of the chest is obtained by a tape measure, the transverse and antero-posterior diameters by *callipers*. The actual shape can be obtained by a *cyrtometer*, consisting of two long pieces of soft metal, joined loosely together by one end of each.

By inspection also, apart from changes in the shape and symmetry of the thorax, we may note the character of the respiratory movements. The normal frequency of respiration in adults is from about fifteen to eighteen in the minute; in children it is much more rapid; it may be thirty or more and varies with the age. In different forms of disease, both pulmonary and of other origin, the movements may be slower or more rapid, shallower or deeper, feebler or stronger than is normal, and they may be irregular. *Dyspnœa* is a clinical term used to indicate "shortness of breath"; it is the patient's own realisation that increased respiratory effort is necessary; there may be (a) increase in the respiratory rate (*polypnœa*); (b) increase in the respiratory volume (*hyperpnœa*); (c) obstruction to

sternum, the first costal cartilages at their junction with the sternum, and a diamond-shaped space at the back in the middle line, including the seventh cervical and first dorsal spines. Elsewhere the vesicular murmur is always present as long as the lung is healthy and the air passages are pervious. In children the vesicular murmur is louder and harsher than in adults (puerile breathing). In adults the vesicular murmur over a healthy lung may be harsh and exaggerated when the other one is put out of action (*compensatory breathing*). The breath sounds may be weak in shallow breathing, in emphysema, and when the chest wall is thick. *Interrupted* or *cog-wheel breathing* is where the inspiratory murmur is jerky or wavy, from irregular expansion of the lung, of which the cause may be mechanical obstruction to the entry of air or irregular muscular action from nervousness. It is not of much diagnostic significance.

Diminished vesicular murmur, deficient entry of air, or absence of breath-sounds, occurs if the air vesicles are obliterated or if the bronchus communicating with them is obstructed or obliterated, or if the air vesicles are displaced from the surface of the chest as is commonly the case in pleural effusion. In the latter case the absence of breath sounds depends on the principle that when sound travelling in one medium, such as air, reaches the boundary surface of another medium, such as a pleural effusion, it is badly transmitted across it, most of it being reflected back again. This is a sign of great diagnostic importance when the breath sounds are normal at the corresponding point of the opposite lung.

Bronchial breathing is a double sound produced in the glottis during respiration, modified by resonance in the mouth, pharynx and bronchial tubes. It can be heard by listening over the trachea. The inspiratory and expiratory sounds are of equal lengths; they are distinctly separate from one another, and are harsh in quality. They may be imitated by placing the mouth and tongue in the position to pronounce the German "ch," and then blowing in and out. As heard over the lung bronchial breathing may be high-pitched (*tubular*), medium-pitched or low-pitched (*cavernous*). The loudness of the sounds is unimportant. Tubular breathing which is heard particularly over hepatised lung has a special blowing or "whiffing" quality. Cavernous breathing has a hollow quality. It is often heard over cavities in the lung, but it does not always indicate that there is a cavity. Bronchial breathing when heard over the chest means that the lung tissue has been modified, mostly by a conversion of the spongy tissue into solid tissue, either by filling up or destruction of the air cells (pneumonia, phthisis), or sometimes by compression from without (pleuritic effusion), if the air passages are not entirely obliterated. The necessary condition is patency of the bronchial tubes with consolidation of the surrounding lung, so that the glottic sound is conducted to the surface, instead of becoming diffused, while the alveolar part of the ordinary respiratory murmur is absent.

Amphoric breathing. This is a double sound heard during inspiration and expiration, more musical than bronchial breathing. It may have a peculiar metallic or ringing character. It may be imitated by blowing softly into the mouth of a narrow-necked glass jar or vase. It is heard over large cavities or a pneumothorax in open communication with a bronchus, and is due to the resonance of the cavity. The pitch and loudness of amphoric breathing are variable.

Stridor is a loud sound rather similar to tubular breathing, but it has a characteristic whistling or hissing quality. It is produced by constriction of the glottis, trachea, or one main bronchus. It is audible over the greater part of the chest, and can sometimes be heard by those near the patient without the aid of the stethoscope.

Adventitious Sounds are heard in addition to, and at the same time as, the ordinary breath sounds or the breath sounds modified as above. If they are not heard with tranquil breathing, the patient should inspire deeply, when they

may become audible. The adventitious sounds are *rhonchi*, *râles*, and *friction sounds*.

Rhonchi are more or less musical sounds, due to obstruction of the bronchial tubes by accumulation of mucus, swelling of the mucous membrane, or spasmodic contraction of their muscular fibres. The sounds vary very much according to the size of the bronchial tube and the extent of the narrowing, and are likened to various familiar sounds, such as cooing, groaning, snoring, grunting, or whistling. The lower-pitched, snoring sounds are called *sonorous rhonchi*, and are produced in the larger tubes; the higher-pitched, whistling sounds are called *sibilant rhonchi*, and are produced in the smaller tubes. They may be heard with expiration or inspiration, and are constantly changing in position and loudness. Loud sonorous rhonchi are often audible to those standing near the patient, and constitute "wheezing."

Râles are various forms of crackling or rattling sounds, which are produced in the large, medium-sized and smaller bronchial tubes, or in pulmonary cavities by the air forcing its way into fluid secretions accumulated there, and thus causing bubbles to form and burst with a slight noise. They are sometimes distinguished as *moist* sounds from rhonchi or *dry* sounds; but this is undesirable, as rhonchi may themselves be due to the presence of mucus. The râles differ according to the size of the bubbles, and are called *fine*, *medium*, and *coarse*. Râles are also divided into *bubbling* and *crackling*; the latter have a sharp, clear, ringing, explosive character, which is probably due to their occurrence in the midst of consolidated lung, and to consequent special conditions of resonance; the former, or bubbling râles, are dull, not ringing or explosive, and occur mostly in tubes surrounded by normal spongy tissue. Crackling râles are sometimes called *consonating* from their supposed acoustic origin, and bubbling râles *non-consonating* in contrast. A *gurgling* râle is a coarse râle which is produced in the largest tubes.

Crepitation is a term which has been used indiscriminately for all râles, but is now generally confined to a very fine râle, so fine as to be suggestive of an origin in dry materials (rubbing of hair close to the ear, or rustling of silk). It is heard in the early stage of pneumonia, in œdema of the lung, and in lung that is forcibly expanded after prolonged collapse. It is probably due to the opening up of respiratory bronchioles, atria and air-sacs, which have been adherent by sticky fluid or from simple disuse. Crepitations and the finer râles are heard only during inspiration; medium-sized and coarser râles may be heard during expiration also. In phthisis râles may be revealed during the deep inspiration that follows a cough.

Metallic tinkling is applied to sounds of a tinkling or ringing character, sometimes heard when a patient with a large cavity breathes, or speaks, or coughs. It is usually a musical râle.

Post-tussive suction is a sucking sound heard over a cavity (tuberculous or bronchiectatic) following a cough; it is due to the air being suddenly sucked back into the cavity with a hissing sound at the beginning of the succeeding deep inspiration.

In cases of hydro-pneumothorax or pyo-pneumothorax, if the patient be shaken while the physician's ear is applied to the chest, a *splashing* sound will be heard which proceeds from the air and liquid in the pleural cavity (*Hippocratic succussion*).

Friction sound, or *pleuritic rub*, is produced by the rubbing together of two pleural surfaces roughened by inflammation. In its most characteristic form it is a rough, grating, or creaking sound, like that which may be heard on forcibly dragging two pieces of leather over one another, or on rubbing the palmar surface of a finger over a wooden surface. It is best heard during inspiration, but may be heard with expiration also. Some friction sounds resemble râles very closely; but they are localised to a small part of the chest, and are not influenced by

coughing. Their loudness varies, when the pressure of the stethoscope against the chest wall is altered. When they arise in the pleura overlying the heart, they correspond with the heart beats, but their loudness varies with the phases of respiration (*pleuro-pericardial friction*).

Voice Sounds. The voice sounds heard with a stethoscope over the normal chest have a "blurred" or indistinct quality owing to irregular conduction through the alveolar tissue. It is to this quality of indistinctness that the term *vocal resonance* is applied. *Diminished or absent vocal resonance.*—In children and females with voices of high pitch, the vocal resonance may be slight or absent. In disease its absence is produced by obstruction of the bronchus, or compression of the lung by fluid. *Bronchophony.*—This term is used when the voice sounds are distinct in quality and, at the same time, louder than usual. When the sounds are distinct but faint the term *distant bronchophony* may be used. Bronchophony is obtained in consolidation of the lung, such as occurs in pneumonia and phthisis, and sometimes when there is great compression of the lung. When bronchophony is present whispered sounds will also be conducted through the lung (*pectoriloquy*). *Ægophony* is a peculiar *nasal* or *twanging* modification of the voice when heard through the chest. It derives its name from its resemblance to the bleating of a goat. Its most common cause is undoubtedly the presence in the pleura of a liquid. Sometimes it may occur in pneumonic consolidation. The explanation of ægophony, most generally accepted, is that the spoken voice is not a pure tone, but a mixture of a fundamental notes and its harmonics of higher pitch. It is well known that low notes are not so well transmitted as high notes from air to liquid, and so it is considered likely that the fundamental note fails to get through the liquid and the harmonics are chiefly heard on the surface of the chest. It is best brought out by asking the patient to utter words containing the vowels "e" and "i," such as "three," or "ninety nine," which depend on the presence of the higher harmonics.

Auscultatory Percussion. In this process a stethoscope is placed on the chest, and the surface is percussed around it; its chief value is to elicit the *bell sound* or *bruit d'airain* in cases of pneumothorax. While the physician listens with the stethoscope to one part of the chest, presumed to be the subject of pneumothorax, an assistant lays one coin on the chest and strikes it with another. The noise is resonated in the hollow cavity, and transmitted as a loud ringing musical note through the stethoscope (*see also p. 191*).

TRACHEITIS AND SPECIFIC INFECTIONS

Inflammation of the trachea arises from circumstances similar to those producing laryngitis. Acute catarrhal tracheitis frequently accompanies laryngitis and bronchitis, but is masked by the symptoms which they produce. Occasionally it exists alone. It then produces cough, often hacking, perhaps violent or paroxysmal, with some amount of expectoration. At the beginning of influenza the tracheitis may be accompanied by substernal pain of unknown origin. With the laryngoscope the mucous membrane may be seen to be congested, and ulcers are sometimes observed. With the stethoscope mucous râles may be heard in the trachea, but the swelling of the mucous membrane and the mucous accumulation are not generally sufficient to cause much dyspnoea. The patient requires treatment similar to that used in bronchitis—warm temperature and avoidance of exposure; troublesome cough may be relieved by insufflations of morphia ($\frac{1}{16}$ to $\frac{1}{8}$ grain); and expectorants, such as squill and ipecacuanha, steam or benzoin inhalations, and the application of mustard to the upper part of the sternum, are of service.

The trachea is attacked by *diphtheria*, spreading from the larynx. Croup, which is no other than laryngeal diphtheria, was at one time supposed to be mainly a tracheitis.

Tubercle of the trachea occurs occasionally in association with tubercle of the larynx ; ulceration follows the deposit of tubercle in the mucous membrane or submucous tissue. The ulcers are more common on the posterior wall, and usually measure from 2 to 4 mm., but may reach 10 mm. in diameter. The symptoms due to tracheal tubercle are generally masked by those to which simultaneous disease of the larynx or lung gives rise.

Syphilis, in its secondary and tertiary stages, also affects the trachea, producing in different cases congestion, condylomas (rarely), and superficial ulcers. The most important change, however, is stricture. The trachea is affected most often at its lower end, less commonly at its upper end ; and the stricture may consist simply of a narrowing at one spot, or a considerable length of the trachea may be reduced in calibre. The mucous membrane is raised into bands and ridges, which have been regarded as cicatrices of former ulcers, possibly preceded by gummas ; but German pathologists look upon the thickening as a direct result of the syphilis, and the ulceration as secondary. In later stages the cartilaginous rings have been exposed, necrosed, and expectorated or absorbed. The stricture can be sometimes seen below the glottis by means of the laryngoscope. For the symptoms, diagnosis, and treatment of stricture, see below under Tracheal Obstruction.

NEW GROWTHS IN THE TRACHEA

The trachea is remarkably little subject to primary new growths, whether benign or malignant. When present they give rise to dyspnoea, and may be recognised by the use of the laryngoscope or bronchoscope. More frequently carcinoma of the œsophagus or of the mediastinum grows into the adjacent trachea, narrowing its channel and producing symptoms of stricture. When it spreads from the œsophagus, it is preceded by dysphagia ; but tracheal symptoms may be the first indication of carcinoma of the mediastinum. Another way in which tumours affect the trachea is by compressing it from outside.

As the chief symptoms in all these cases depend on the reduction of the calibre of the trachea, and as this may be due to other causes besides such tumours, it will be well to consider separately the pathology and clinical features of tracheal obstruction.

TRACHEAL OBSTRUCTION

The causes may be grouped under three heads : (1) compression from without ; (2) changes in the walls of the trachea itself (stricture) ; (3) foreign bodies within it.

Compression of the Trachea. The most common causes are mediastinal new growths, aneurysm of the aorta or large vessels, enlargement of the thyroid body, and malignant tumours in the neck. Carcinoma of the œsophagus may also compress the trachea, but soon invades it, so that perforation takes place between the two tubes. Occasionally in children caseation and suppuration of the bronchial glands may lead to their enlargement, by which the trachea is compressed ; and if the abscess bursts into the trachea, pus or portions of caseous glands may be expectorated. A mediastinal abscess arising in any other way (caries of the spine, localised empyema), the dilated left auricle in cases of mitral stenosis, and in children an enlarged thymus, are occasional causes of tracheal compression.

Stricture. The chief cause is syphilis, which has been already considered.

Foreign bodies are rarely retained in the trachea, but commonly fall into one or other bronchus, though they may be driven up and down the trachea by the respiratory currents.

Symptoms. The most important are dyspnoea and stridulous breathing ; they are often accompanied by cough and the expectoration of thin frothy mucus. The voice is unaffected, or it is feeble because the obstruction weakens the current of expired air. The chest is resonant, but vesicular murmur is faint, or drowned

by the noise of the stridor. Other symptoms accompanying tracheal stenosis are due to the lesion which causes it, and these may be at first entirely absent in a case of aortic aneurysm or deeply seated mediastinal tumour.

When the tracheal stricture or compression has reached a certain limit, the patient becomes liable to sudden attacks of aggravated dyspnoea with cyanosis. From a few of these paroxysms he may recover, but in the third or fourth or a later one he will probably die.

Diagnosis. This has to be made (1) between obstruction in the trachea and obstruction in the larynx; (2) between the different causes of tracheal obstruction.

The laryngoscope will show at once the absence of laryngeal disease; the presence of tracheal stricture, or of tumour or aneurysm compressing the trachea, may also be demonstrated by the laryngoscope, or, failing that, by the bronchoscope. This point should be determined, if possible, before the occurrence of the paroxysms above mentioned, in which the use of these instruments may be difficult, and which, moreover, may wrongly suggest laryngeal spasm and lead to a hasty and useless tracheotomy. There are some differences in the effects of laryngeal and tracheal obstruction. One is the fact, noticed by Gerhardt, that in laryngeal obstruction the larynx is moved extensively up and down in the neck during respiratory movements, whereas in tracheal obstruction it moves but slightly. In laryngeal obstruction the head is thrown back; in tracheal obstruction it is often bent forward. If the laryngeal obstruction is due to abductor paralysis, the stridor is chiefly inspiratory, whereas in tracheal obstruction there is generally some stridor with expiration. But in other cases of laryngeal obstruction the stridor occurs with both respiratory acts. Auscultation of the trachea is certainly deceptive, as the loudest stridor is heard over the larynx even when the stenosis is in the trachea. The point is of practical importance, because laryngeal obstruction may be relieved by tracheotomy, but tracheal obstruction rarely so; and it is desirable to spare the patient an operation of this nature when it can do no possible good. But a new growth or aneurysm in the neck or upper part of the chest may produce the two obstructions, namely, one directly, by pressure on the trachea, the other indirectly, by pressure on the recurrent laryngeal nerves so as to cause abductor paralysis.

Apart from the assistance rendered by the laryngoscope or the bronchoscope, the recognition of the cause of tracheal obstruction must depend upon collateral symptoms. Any source of compression would probably involve other organs and thus cause dysphagia, obstruction of the veins of the head, neck, or arm, pressure on corresponding nerves, and dulness under the sternum, or at the upper part of the chest on one side. On the other hand, stricture due, as already stated, to syphilis must be free from such symptoms; but an aneurysm of the aorta may compress the trachea without at first any other symptom by which it can be recognised. For the diagnosis of intra-thoracic growth from aneurysm the reader is referred to *Intra-thoracic Neoplasms* (see p. 181). The Röntgen rays may in either case render some assistance.

Prognosis. This is very unfavourable, the commoner causes being little amenable to treatment; but the rare cases of abscess compressing the trachea may recover on the bursting of the abscess.

Treatment. The indications are (1) to remove the cause, if possible; (2) to open the trachea below the obstruction where this is in the upper part; and (3) to relieve symptoms and secondary results. A diseased thyroid or hypertrophied thymus may be removed, and enlarged glands or growths in the neck; and abscesses, where accessible, may possibly be opened; but such opportunities are infrequent. If an aneurysm is diagnosed, the treatment for that condition should be employed, and for obvious stricture active antisiphilitic treatment by means of mercury and potassium iodide or salvarsan, especially if a positive Wassermann reaction is obtained. The iodide may be employed in any case

which does not present sufficient data for a positive diagnosis as to the cause of the obstruction. In the case of a foreign body, tracheotomy should be performed, and then efforts to dislodge it should be made by inversion of the patient or shaking, or by the use of special forceps through a bronchoscope.

BRONCHITIS

Ætiology. Bronchitis may occur as a primary infection, and it is then probably one form of the "common cold" described on p. 195, and the bacteriology and mode of infection are the same. This type of bronchitis is often associated with, or followed by, inflammation of the larynx and nasal mucous membrane, or the inflammation may commence in the latter, and spread downwards to the bronchi. In fact the section on coryza should be read in connection with bronchitis. Another cause is contact of the bronchial mucous membrane with irritating vapours, or air carrying solid particles, such as dust, fog, or cold, damp and changeable climates, or the air of mines and of certain manufactories. Bronchitis may also be set up by the presence of foreign bodies actually in the bronchial tubes; this is comparatively rare, but blood effused into the tubes may act in this way, and it constantly occurs as a result of the deposit of tubercle or carcinoma in the substance of the lung. Bronchitis may be due to infection by any of the catarrhal organisms which are present in the sputum, such as the pneumococcus, Friedlander's pneumo-bacillus, streptococci, *M. catarrhalis*, staphylococci, *M. tetragenus*, and occasionally *Bacillus coli communis*. Bronchitis may also be secondary to focal infection of any kind, and especially to sinus disease. Certain infectious diseases are frequently accompanied by bronchitis—namely, typhoid fever, measles, diphtheria, influenza and whooping-cough; and it often occurs in Bright's disease. The relation of bronchitis to asthma is described later.

Bronchitis is especially prevalent amongst infants, young children, and elderly people, whereas young adults and the middle-aged are much less subject to it. Habits of luxury, confinement to warm rooms, and undue wrapping up, render the subject liable to contract bronchitis on comparatively slight exposure; and those in weakly health, or depressed from insufficient food, exhausting occupations, or bad sanitary conditions, easily acquire it. Heart disease, impeding the circulation in the lungs, is a predisposing cause. Bronchitis is much more common in winter than in summer. Chronic bronchitis may follow a single attack or repeated attacks of acute bronchitis; and acute bronchitis may supervene on chronic bronchitis.

Pathology. The mucous membrane is the part most affected, but in severe or prolonged cases the submucosa is involved, and rarely the cartilages of the bronchial tubes, and adjacent parts of the lungs. The first effect is increased vascularity and swelling of the mucous membrane, and after a short time a free secretion from the surface takes place. It is a clear fluid containing mucus; but in it there are also leucocytes and shed epithelial cells. In later stages the secretion becomes more opaque and yellow from the presence of increasing numbers of leucocytes. The secretion may also contain cells in a state of fatty degeneration, or cells containing particles of soot or dirt derived from the inspired air.

In fatal cases the tubes are often seen to be filled with greenish pus (*purulent bronchitis*). Sometimes the smallest tubes are affected. If the superficial part of the lung be sliced off, and the exposed section be squeezed, minute drops of pus will be found to ooze freely from the cut surface. The condition is one of *capillary bronchitis*, or *bronchiolitis*. Fraenkel describes a *bronchiolitis fibrosa obliterans* occurring in workmen exposed to irritating air or dust; the bronchioles are obstructed by acute or subacute growth of connective tissue.

If, in ordinary catarrhal cases, the inflammatory process persists long enough,

the fibrous coats of the bronchi become thickened, and infiltrated with leucocytes; the muscular fibres are atrophied by pressure; and the cartilages and mucous glands disappear from the same cause. Ultimately, in many cases, the bronchial tubes become dilated, and form fusiform or cylindrical wide channels, often reaching the surface of the lung (*bronchiectasis*).

As a result of bronchitis the lung itself undergoes important structural changes. Acute capillary bronchitis may lead to *lobular collapse* and *broncho-pneumonia*; chronic bronchitis is followed by *vesicular emphysema*, and sometimes by *chronic interstitial pneumonia*. The last three will be spoken of separately.

Lobular collapse occurs in isolated lobules when the bronchial tubes leading to them are blocked with mucus, since when a tube is plugged the retained air, being stagnant in contact with the pulmonary capillaries, undergoes absorption, just as air is absorbed which has escaped into the subcutaneous cellular tissue.

There is experimental evidence (7), obtained by examination of the arterial blood, that the dyspnoea present in severe cases of bronchitis is due to a retention of CO_2 and deficiency of oxygen, probably brought about by bronchial spasm.

Physical Signs. On *inspection* the breathing is seen to be quickened, the chest is symmetrical, and generally in a state of moderate over-distension. The accessory muscles of respiration are seen to be in strong action, and expiration is prolonged. There may be sucking in of the intercostal spaces during inspiration. *Percussion*, as a rule, yields a normally resonant note, but there is occasionally slight hyper-resonance from temporary over-distension of the air vesicles; there may be impairment of resonance at the bases from accumulated secretion or from collapse. *Auscultation* shows that both inspiration and expiration are accompanied by *sibilant* or *sonorous rhonchi*, depending on the size of the tubes affected, or various kinds of *râles*, or both combined. The coarser rhonchi are often felt by the hand placed upon the chest, and may be even heard by the patient himself, or those standing near him. The larger or coarser râles are heard with both expiration and inspiration, the finest râles only with inspiration. These sounds are not equally present in all cases or in all stages of the disease. In many cases rhonchi alone are present. In severe cases the sounds are heard, variously mixed, over the whole chest, and may entirely drown the vesicular murmur. With spasm of the bronchial muscle there is marked prolongation of expiration.

Symptoms of Acute Bronchitis. At the beginning there is malaise, and a sensation of tightness of the chest; and cough occurs with little sputum. In mild cases the general disturbance may be but slight, and the illness is confined to cough. In severe cases there is slight fever, the temperature rising to 100° or 101° , the appetite failing, the tongue furred, the bowels inactive, and the urine scanty. The cough is at first hard and dry, and is often attended with pain behind the sternum and in the muscles of forced expiration from the strain put upon them. The expectoration is then but scanty, consisting of thin, frothy mucus, with possibly an occasional streak of blood. After a few days the cough becomes easier and looser, and the expectoration is more abundant, more opaque, and yellow and green, from the addition of increasing quantities of leucocytes. In slighter cases the expectoration is generally more in the morning, from the accumulation during sleep, and in towns this sputum is frequently black with pigment derived from the atmosphere. Dyspnoea is often considerable, and the patient has to sit upright in bed (*orthopnoea*), and all the respiratory muscles are called into play. After a time the secretion of muco-pus becomes less, the cough is less frequent, and the symptoms gradually subside. When the smallest bronchial tubes are filled with purulent secretion in the form above described as a capillary bronchitis, the position is one of extreme danger, especially in quite young children. There is severe dyspnoea, great cyanosis or lividity of the face and extremities, and rapid exhaustion. The cough is at first frequent, with abundant expectora-

tion of viscid glairy mucus, or muco-pus, or pus. In later stages the patient becomes livid and drowsy; the pulse is feebler and quicker; inspiratory efforts are less effectual; and the intercostal spaces are more sucked in. Expectoration gradually diminishes; and before death the disturbance of the cerebral circulation is shown in coma, often with a slight amount of delirium.

Symptoms of Chronic Bronchitis. The main features are not essentially different from those of the acute form; but there is an absence of fever and the constitutional disturbance which occur in acute attacks, and after long continuance secondary results of a permanent kind are produced. In the lung itself, emphysema and dilatation of the tubes (*bronchiectasis*) take place, and these will be described later. But the effects are felt beyond the lung; the emphysema (*q.v.*) impedes the pulmonary circulation, and the right heart becomes hypertrophied; it may eventually dilate, and thereupon the general venous system suffers, so that œdema of the lower extremities, congestion of the liver, ascites, and albuminuria occur. Under such circumstances tricuspid regurgitation often takes place, with its characteristic murmur (*see Diseases of the Heart*). Long-continued and severe chronic bronchitis has a serious effect upon the strength of the patient. In consequence of disturbed sleep, abundant expectoration, and impaired digestion, nutrition fails, and there may be considerable emaciation. In some cases also, in this late stage, febrile reaction of a hectic type may set in. The varieties of chronic bronchitis commonly described are the following:

1. By far the larger number of cases come under the head of ordinary *winter cough*, occurring as above mentioned. The cough is variable, sometimes coming on in paroxysms, generally worse at night; and in the morning also there is often severe coughing to expel the secretions which have accumulated during the period of rest. According to the severity or extent of the affection, the expectoration may be slight in amount, thin, mucous, and frothy, and containing black pigment in the morning; or it may be yellow or yellowish green and mucopurulent, with very little air; or it may be entirely airless, liquid, green pus. The sputa in this case generally run together in the vessel, and do not exhibit the *nummular* character common in phthisis. Microscopically, besides the abundant pus cells, there are epithelial cells containing fat, and non-pathogenic micro-organisms. Blood is occasionally present in the expectoration, usually in the form of streaks, but rarely in masses, or in any considerable quantity.

2. *Dry bronchitis*, or *dry catarrh*, is a form of chronic bronchitis in which there is very little secretion. The cough is frequent, violent, and prolonged, so that extreme congestion of the face occurs; but there is either no sputum at all, or only a small quantity of tough mucus. There is much soreness of the chest and considerable dyspnoea from spasm of the smaller tubes.

3. In the rare condition called *bronchorrhœa* or *pituitous catarrh*, the mucous glands bear the chief brunt of the infection. The cough is troublesome and paroxysmal in the endeavour to bring up either a thin or a thick and ropy sputum, which looks like unboiled white of egg streaked with yellowish white plugs from the smaller bronchi, the whole being covered with froth. In a case recently described (8) a pint was expectorated in twenty-four hours, and it was brought up with difficulty in small amounts at a time, each bout of cough ending with the expulsion of one or more of the mucous plugs. But where the total volume measures four or five pints large quantities may be brought up at a time with comparatively trifling effort. The condition may be distinguished from œdema of the lung by the yellow or amber colour and high albuminous content of the fluid in the latter case after removing the froth from the top.

4. *Putrid* or *fœtid bronchitis* is characterised by very offensive sputum, which mostly occurs in cases where the tubes are dilated. The sputum is abundant and rather thin, and in the sputum vessel it often separates into three layers, of which the uppermost is frothy with mucus, the middle a thin sero-mucous fluid, and the lowest a thick layer of pus containing the bodies known as Dittrich's or

Traube's plugs. These are whitish grey or dirty greyish yellow, varying in size from a millet seed to a bean. Under the microscope they are seen to consist of pus corpuscles, detritus, bacteria, bundles of fine acicular crystals of palmitic and stearic acids, and twisted threads of leptothrix. The chemical contents of the sputum are acetic, butyric, and valerianic acids, leucin, tyrosin, sulphuretted hydrogen, and methylamine. The condition is to be distinguished from gangrene of the lung. Very offensive sputum may also proceed from an empyema opening into the lung, and occasionally from an old tuberculous cavity.

5. *Plastic, fibrinous or croupous bronchitis*. This rare affection is characterised by the expectoration of casts of the bronchial tubes. The sputum is generally in the form of a rounded mass, covered with mucus or blood, and, when frayed out in water, one sees a more or less perfect branching cast of a portion of the bronchial tube system. The cast is not generally thicker than a goose quill, and varies from $1\frac{1}{2}$ to $2\frac{1}{2}$ inches in length, and only rarely reaches 4 or 5, or even 7 inches. It has a grey or whitish yellow colour, and consists of concentric laminae, which do not usually fill up the lumen of the tube, so that the casts are not solid, except those from the smallest tubes. Under the microscope the cast has a fibrillated structure, with numerous embedded leucocytes, streptococci and staphylococci, hæmatoidin crystals, Curschmann's spirals and Charcot-Leyden crystals (see p. 141). The patient is seized with violent attacks of coughing, often suffocative in character, with more or less pain or oppression at the chest, and attended at first with no sputum, unless perhaps a little mucus. After a time—it may be a few hours, or as long as two or three days—a bronchial cast is brought up. Relief is generally at once afforded: the cough subsides or disappears. But it commonly recurs in a few hours, and casts may continue to be expectorated, at intervals of a day or so, for several days, when the patient gradually gets quite well. Hæmoptysis occurs in some cases, usually after the expulsion of the cast. The physical signs are those of obstruction of a bronchus, with râles as the casts are becoming loosened. Plastic bronchitis is rarely fatal, except from complications; but it recurs at irregular intervals over a period of several years.

6. Chronic bronchitis associated with *polycythæmia rubra* (Ayerza's Disease) is the result of long-continued oxygen deficiency, and this leads to increase in the hæmoglobin of the blood, the number of red cells may approximate to 10,000,000 per cubic millimetre, and there may be clubbing of the fingers. The patient is very cyanosed, and in one case the arterial blood was found to be only 79 per cent. saturated with oxygen, instead of the normal 95 per cent. However, the actual amount of oxygen carried by the blood was about normal, owing to the great increase in the hæmoglobin and red cells. The arterial CO₂ pressure was also increased, and the patient was very breathless (7). Males are more commonly affected than females, and the Wassermann reaction is often positive. There is great hypertrophy and dilatation of the right ventricle, and this is indicated by the electrocardiogram; there is dilatation and atheroma of the pulmonary artery with engorgement of the lungs—evidence of high pulmonary blood pressure.

Diagnosis. The diagnosis of bronchitis depends on the presence of rhonchi or râles. The dyspnoea and physical signs in *asthma* are like those of a very acute bronchitis, but the history of its occurrence and of former attacks will help to distinguish it. In the capillary bronchitis rhonchi are generally quite absent, and these cases are recognised by the lividity, drowsiness, and presence of râles. Rarely obstruction of one bronchus (see p. 144) may cause a stridor which is mistaken for a bronchitic rhonchus. Often there is difficulty in excluding chronic phthisis, for phthisis is often accompanied by bronchitis. Here the occurrence of febrile reaction, of hæmoptysis, of rapid wasting, and the greater intensity of the physical signs on one side or at one apex, would be in favour of phthisis, and confirmation may be obtained by examination of the sputum for bacilli, by the use of X-rays, or of tuberculin (see Phthisis).

It remains to determine whether an acute bronchitis is a primary infection or secondary to such disorders as whooping-cough, measles, typhoid, or other specific fever. In children acute miliary tuberculosis must be thought of.

Prognosis. *Acute Bronchitis.* The duration is from a few days to three weeks or more. In fatal cases of purulent or capillary bronchitis it is from nine to twelve days. *Chronic bronchitis.* Though it frequently shortens life, many people live to an advanced age in spite of it. It is mostly affected by the season in a marked manner, and patients are often practically well during the summer, and again get ill in the winter; but they are worse with each succeeding winter, and finally may be carried off during an exceptionally severe season, or during the cold fogs of towns, or during east and north-east winds elsewhere. On the other hand, if they can be protected from this unfavourable weather by confinement to the house, or better, by residence in a warmer climate, they may keep their bronchitis within limits, and postpone the fatal termination for years. Its ill effects will, however, vary with the amount of secretion and with the rapidity with which the secondary results—emphysema, dilated tubes, and dilatation of the right heart—are developed.

Prevention. This depends on avoiding sources of infection and the causes predisposing to infection in individual cases. Susceptible people must avoid others suffering from catarrh. If contact is necessary gauze masks may be worn as described for influenza. Various measures described under the prevention of coryza (*see* p. 196) may be used in suitable cases. Stock vaccines or auto-genous vaccines are often useful. The latter may be prepared from the sputum, but cultures should also be taken from the nose, where the organism chiefly responsible may often be obtained in pure culture. The English winter climate with its cold and damp is a very common predisposing cause of bronchitis, but residence in places in the south of England such as Bournemouth, Ventnor, Torquay or Penzance may produce favourable results. There are also favourable climates abroad, and Mentone, San Remo, Cannes, Arcachon, Canary Islands, Madeira, and the Nile (Assouan) are the places most frequented by patients.

Treatment. In cases of moderate severity the patient should be placed in bed in a warm room. In less severe cases the patient, though allowed up, must be guarded from exposure, and kept as far as possible in a uniform temperature of 60° or 65° F. In chronic bronchitis removal to a favourable climate may have to be considered (*see* Prevention). If there is much tightness of the chest, counter-irritation by means of antiphlogistine, mustard leaf, or a linseed meal poultice sprinkled with mustard, should be employed. In children, counter-irritants should be used with care, but a thin poultice surrounding the whole chest (jacket poultice) is of great service. The diet should be light and nutritious.

There are three motor mechanisms that keep the air passages free from obstruction, viz., for the larger bronchi the propulsive movement of the ciliæ and the expulsive mechanism of the cough, and for the smaller bronchi muscular peristalsis; but of equal importance is a good flow of bronchial secretion, which acts both as a lubricant and as a diluent of irritating substances. At first, when the cough is dry, sedatives, such as tinct. camph. co, are indicated, and later expectorants. Ammonium carbonate (5 grains every four hours), vinum ipecacuanhæ (5 to 10 minims), and tinct. scillæ (15 minims) irritate the gastric mucous membrane, and by reflex vagal action increase the bronchial secretion. The latter is increased still more if the drugs are pushed to the extent of causing emesis, and this is sometimes made use of in treating children, *i.e.* a drachm of vinum ipecacuanhæ, repeated in fifteen minutes if necessary, is given to get rid of accumulated bronchial secretion. Squill is of particular value in chronic bronchitis owing to its digitalis-like effect on the heart. A second class of expectorants stimulates secretion by being excreted by the bronchial glands. The most important member of this class is potassium iodide in doses of 5 grains; it is particularly valuable in chronic bronchitis. Where the expectoration is abundant, the balsams of Peru (20 minims suspended

with $1\frac{1}{2}$ drachms of honey) and tolu should be given, or ammonium chloride (5 to 20 grains). Where the sputum is foetid, terebene (5 to 15 minims) may be tried; 5 drops on sugar, taken several times a day, is useful for winter cough. In young children, who have but little power of expectoration, the secretions in capillary bronchitis may be so abundant as to threaten to fill up the tubes and cause suffocation. Tinct. belladonnæ, in doses of 3 to 5 minims, or injections of atropine, $\frac{1}{500}$ grain, are given to paralyse the secretory glands and dry up the tubes. The same treatment may also be useful in adults. When the cough is very irritating, sedatives may be employed—morphia in small doses ($\frac{1}{8}$ grain or $\frac{1}{4}$ grain), compound tincture of camphor ($\frac{1}{2}$ drachm), heroin ($\frac{1}{10}$ grain to $\frac{1}{20}$ grain), codeine phosphate ($\frac{1}{4}$ grain), or potassium or ammonium bromide (5 grains). But they must be used with great care if there is much lividity, as they may dangerously depress the respiratory and cardiac centres under these circumstances. Hydrocyanic acid, which is contained in the commonly prescribed syrup of Virginian prune, is a sedative, and probably acts by paralysing the vagal nerve endings in the stomach—the converse of ipecacuanhæ—and is valuable in “stomach cough.” Cases accompanied with much spasm of the bronchial tubes may be benefited by tinct. stramonii or tinct. lobeliæ æth. (15 minims), ether (15 minims), or tinct. cannabis ind. (10 minims). Chloral in small doses (5 to 7 grains) has also been recommended. Some of these methods of treatment might appear to be opposed to another. Actually, good results are obtained by combining them, as for instance in the Linctus scillæ co. (B.P.C.) (dose 1 drachm), which contains equal amounts of the sedative tinct. camph. co., and of the expectorants oxymel scillæ and syrup. tolutanus. Again, stramonium or lobelia are commonly prescribed with potassium iodide, while the elixir diamorphinæ et terpini (B.P.C.) (1 drachm) contains terpin hydrate, heroin and syrup of Virginian prune—one expectorant and two sedatives.

In all severe cases with cyanosis (or dyspnœa), oxygen inhalations may render valuable service (see p. 156). Good may be derived from keeping the air of the room moist by steam issuing from a “bronchitis kettle,” or from medicated inhalations such as vapor benzoini (1 drachm tinct. benzoini co. in 1 pint of hot water to be inhaled from a special inhaler or an ordinary jug). The following preparations are useful when the sputum is abundant or foetid: Vapour olei abietis (B.P.C.) (1 drachm to $\frac{1}{2}$ pint); the dry inhalations, vapor cresol. co. (B.P.C.), a small quantity of the fluid being poured into a metal vessel and volatilised by heat; vapor iodi. æthereus (B.P.C.), by means of an oro-nasal respirator; vapor ammonii chloridi (B.P.C.) If the bronchitis can be referred to any constitutional disease, this should, of course be treated at the same time—for instance, gout by the exhibition of alkalies and colchicum. Many cases require tonics, such as quinine and cod-liver oil. It is desirable to see that the bowels are freely opened; and in cases of long standing, where the right side of the heart is dilated, the various secretions should be kept free, and the heart’s action assisted by digitalis, as under corresponding conditions in valvular disease. Vaccines are of value when the predominating organism is *M. catarrhalis* or Friedlander’s bacillus, or when focal infection is the primary cause.

BRONCHIECTASIS

Ætiology. Bronchiectasis, or dilatation of the bronchi, may occur in connection with many diseases of the lungs. It is often associated with some fibrosis of the surrounding lung tissue (*fibroid lung*), or with *emphysema*.

Any gradually increasing and persistent obstruction of a large bronchial tube is likely to be followed by dilatation of the smaller bronchi proceeding from it. Thus aneurysms pressing on a bronchus, carcinoma pressing on or growing into it, syphilitic stenosis and an impacted foreign body may be the causes of bronchiectasis. But the commonest cause of bronchiectasis is a primary inflammatory

condition, such as bronchitis, long-continued broncho-pneumonia, especially in children, and occasionally lobar pneumonia. Pressure on the lung from the outside by pleural effusions or neglected empyemas may also cause bronchiectasis, associated with fibrosis of the lung. Rarely the condition is congenital; the rare cystic degeneration of the lung may also be mentioned here.

Pathology. In cases of partial obstruction, the tubes beyond become distended, because the inspiratory movements are more effective than the expiratory ones, so that air is sucked in and does not completely escape again. In chronic bronchitis the secretion in the tubes may cause obstruction, and at the same time the walls of the tubes are softened by the inflammation and so readily dilate. Another mode of production has been discovered in severe broncho-pneumonia. The acute bronchitis and peri-bronchial lymphangitis leads to complete destruction of the bronchial wall, which may involve neighbouring alveoli and form a clear-cut cavity, which may be *cylindrical* if a length of tube has been destroyed, or *saccular* if only one side of the tube has met this fate. During healing the cavity becomes lined with young fibrous tissue, and a new epithelium of low cubical cells is formed. In ordinary cases the change affects the medium and smaller tubes, and is more common in the lower lobes than in the upper. The cavities are thin-walled and present generally no trace of the muscular tissue or cartilage of the healthy bronchi—"honey-comb lung"; a small bronchus may often be found opening into the cavity. Sometimes there are bands running along the walls; sometimes the surface is ulcerated, though it is usually smooth. These cavities are frequently associated with the extensive fibroid changes in the lungs (10) (see Plate 1).

Bronchiectasis is often limited to one lung, especially when due to bronchial obstruction, to a foreign body, or to acute pneumonia or pleurisy. If both lungs are affected, either the lesions are not extensive, or one lung is very much more involved than the other.

Symptoms. In cases of moderate cylindrical dilatation associated with bronchitis or emphysema, the symptoms will be lost in those of the primary disease. But in larger dilatations and in the saccular variety the bronchiectasis is the prominent fact in the case, and the secretion from the cavities and the fibrosis and cavitation of large portions of the lung are productive of definite symptoms and physical signs.

The patient need not be emaciated, is generally free from fever, and may be inconvenienced by little besides dyspnoea, cough, and expectoration. But there may be cyanosis and clubbing of the fingers. When there is increased resistance to the pulmonary circulation, failure of the right heart will cause œdema of the feet, enlargement of the liver, and albuminuria.

The sputum is either (1) purulent and airless, or (2) muco-purulent, or (3) foetid, muco-purulent and frothy, like that of foetid bronchitis. When there are one or two large saccular cavities the sputum is often expectorated in a characteristic manner. The secretion collects for some time—it may be two or three hours—in the dilated tubes without exciting cough; then either from its quantity, or because the patient moves about, turns over or sits up in bed, the secretion flows over into an adjacent healthier tube, coughing is excited, and some ounces of muco-purulent secretion are all at once expectorated. In some cases, hæmoptysis is both frequent and moderately abundant.

Dry bronchiectasis is a not uncommon variety, discovered by means of X-ray examination after lipiodol. There is a preceding history of broncho-pneumonia, particularly after measles and whooping-cough; the symptoms are cough with but little non-foetid sputum and hæmoptysis. There is basal impairment with weak breath sounds and râles; there is usually no clubbing. The danger lies in excessive hæmoptysis or the development of wet bronchiectasis (11).

Physical Signs. These differ according to the character and size of the dilatations, their distribution in the lung, and the amount of consolidation or

fibrosis of the intervening lung. In some cases, a large portion of one base, or even the whole of one side of the chest, presents coarse, creaking, and crackling râles, obscuring the respiratory murmur, but without dulness or pronounced limitation of movement. In other cases there is, in addition, an area of impairment where bronchial or amphoric breathing, with bronchophony and pectoriloquy are heard, and other rarer signs of a cavity surrounded by condensed lung tissue (p. 127). When the cavity is full up with secretion, there may be impairment and diminished breath sounds, while râles and bronchial breathing only appear after coughing. In extreme cases the condition resembles chronic pneumonia. Retraction of the chest takes place, the heart is drawn in a horizontal direction towards the diseased lung, and the opposite lung becomes compensatorily emphysematous.

Diagnosis. The diagnosis and the extent of cavitation can be determined by X-ray after injecting lipiodol. The overlying skin, etc., is anæsthetised by injecting 1 per cent. novocaine down to the cricothyroid membrane; 10 minims of 5 per cent. cocaine are injected through the membrane into the trachea, with the patient sitting upright. After three minutes a special curved trocar and cannula are passed through the membrane into the trachea. Air can be drawn through the cannula to make certain that the position is correct. The lipiodol, warmed to 106° F. (30 to 40 c.c. for an adult, 30 c.c. for a child), is drawn into the warmed sterile syringe and injected through the cannula, and then the patient lies on the suspected side. The radiogram is taken in the vertical position (see Plates 1 and 2, A, which shows the normal). If coughed up the lipiodol should not be swallowed. In an adult the lipiodol may be administered over the back of the tongue by means of syringe and catheter (12) or by nasal catheter directed straight into the larynx after applying cocaine. Bronchoscopy, as described under Abscess of the Lung, may be very useful in diagnosis.

The differential diagnosis from chronic phthisis depends on the absence of tubercle bacilli in the sputum, the history of some antecedent infection, e.g. pneumonia, and the site of the cavitation, which is very rarely apical. A basal bronchiectasis may be hard to distinguish from an *empyema* discharging into the bronchi. The history may help, and hæmoptysis is in favour of bronchiectasis. Exploration might yield pus in either case.

Prognosis. As compared with phthisis, it is good; patients often live for years with but slow advance in the local conditions; but they are liable to dangerous complications, such as pneumonia, abscess, gangrene, septicæmia, and the occurrence of cerebral abscess and metastatic abscesses elsewhere.

Treatment. Locally the object should be to assist the evacuation. For this purpose the patient lies in bed on the sound side and the foot of the bed is raised one foot by means of blocks. This drainage is carried out for half an hour daily at first, and the time is gradually increased to two hours a day. The buttocks may be kept in place by a wedge-shaped cushion. The modern method of drainage is by *bronchoscopy* (see Abscess); great improvement may follow, though, as there is structural alteration of the tubes, the patient is liable to later exacerbations. Antisepsis of the bronchi may be tried by giving up to 15 minims of oil of turpentine three times a day by mouth. Inhalations of antiseptics (see Bronchitis) are of value, including the daily inhalation for fifteen to sixty minutes of the vapour of creosote in a closed chamber (Chaplin).

Several surgical methods of treatment have been tried, including surgical drainage of a single large cavity, with or without resection of the overlying ribs; phrenic avulsion, artificial pneumothorax, and subsequently the chest may be filled with olive oil containing 5 per cent. gomenol through a cannula; this will remain unabsorbed for six months so that refills are required at long intervals; excision of the diseased lobe (lobectomy) with occlusion of the bronchus proximal to the cut; resection of ribs overlying the bronchiectatic part of the lung, so that collapse may be allowed to take place.

HAY FEVER; ASTHMA

Hay fever is a very severe catarrh, affecting chiefly the nasal mucous membrane, often the bronchial mucous membrane as well, and causing contractions of the bronchial musculature. *Asthma*, used in its broadest sense, is a term applied to a state of affairs in the smaller bronchi which hinders the exchange of air between the larger bronchi and the alveoli of the lungs. We know little for certain about the nature of the obstruction, but, arguing from the analogy of the plain muscle of the intestine or bladder, we may assume that the bronchial muscle, which possibly contracts slightly during each normal respiration, may in asthma at one time be tonically contracted, and at another time undergo a series of violent rhythmic contractions and relaxations. Œdema or congestion of the mucous membrane also plays a part in the obstruction. From this definition we see that the term asthma is often used to denote a symptom, or perhaps a syndrome, rather than a disease—a syndrome in fact that may be caused by different agents.

The Allergic State. Hay fever and asthma are often different manifestations of the same type of disease, which also includes paroxysmal rhinorrhœa (vasomotor rhinitis); angeio-neurotic œdema; paroxysmal hydrarthrosis; some types of urticaria, eczema, pruritus, prurigo; certain gastro-intestinal disturbances; migraine, and a few cases of epilepsy. The members of the group have been classed together as the *toxic idiopathies*, or the *allergic state*. The patient is sensitised to a particular foreign protein, which acts as a poison, so that a violent reaction is produced. This is very similar to the effect produced by the injection of serum into an individual who has been sensitised to it, and so it has been regarded as of essentially the same nature, *i.e.* *anaphylactic* (see p. 15, where the Prausnitz-Küstner reaction is also described). However, there is this definite fact about anaphylaxis pure and simple, *viz.*, that a preliminary sensitising injection of antigen is always necessary to produce anaphylactic shock, whereas in naturally occurring allergic disease the evidence of such a preliminary sensitisation is not obvious. But it is possible in allergy that the antigen—and only quite small doses are necessary—may have obtained access through an abraded mucous membrane. For instance, during gastro-enteritis, undigested protein, *e.g.* egg protein, may be absorbed from the intestinal tract and so give rise to a permanent state of hyper-sensitiveness to this substance. Also there is reason to believe that gastric digestion and consequently proteolysis are imperfect in these cases, so that proteoses become absorbed directly from the alimentary tract, and that then the liver fails to deal with them as it should (failure of protopexic function), and they enter the general circulation, producing anaphylaxis (46). In allergy there are, no doubt, other factors also present, and nervous factors, light sensitisation and even drugs, undoubtedly play a part, in addition to the protein irritation and the original trauma, through which the protein gained access to the body. For instance, 4 per cent. of asthmatics are extremely sensitive to aspirin and have been nearly killed by quite small doses, and in these people the salicylic acid from a dose of aspirin has been found to accumulate in the blood to a much greater extent than normal (13). Again, there is a strongly inherited tendency to the toxic idiopathies, although members of an affected family may differ as regards the type of allergic disease they manifest, and may indeed suffer from more than one of these.

In the section on anaphylaxis it was pointed out that anaphylactic shock resulted from the interaction of antigen and anti-body in the tissues of the body, and that this interaction caused a breakdown of protein molecules. It is very interesting that in allergic diseases certain biochemical changes have been discovered which favour the theory that the allergic attack is also associated with an excess of proteose in the blood and a resulting anaphylactic shock, causing increased protein catabolism (14). During the attack the liver deficiency is shown

by the blood giving a positive indirect van den Bergh reaction in the blood by the blood sugar being low (45), while at the same time there is a "hæmoclastic crisis," which consists in a fall of blood pressure, a leucopenia, a change in clotting time and in the refractive index of the serum to light. Following from this the content of amino-acid, uric acid and creatinine in the blood rises; there is an increased excretion of these bodies in the urine. Less water is excreted by the kidneys and the urine becomes highly acid; there is a retention of chloride, while the chloride in the red corpuscles is diminished. But most important of all, there appears in the urine a "proteose" (see p. 512), which often produces a specific "skin reaction" when tested on the patient (see later); positive results have been obtained in 50 per cent. of asthmatics whose skins are sensitive to proteins derived from foods or inhalants, but in only 15 per cent. of other asthmatics. Healthy men rarely react to their own proteose, though 32 per cent. react to asthmatic proteose, which is clearly toxic (47). After the attack the blood becomes normal; there is also a marked diuresis, so that the urine may become actually alkaline. The writer would suggest that the protein catabolism resulting from the anaphylactic shock liberates many smaller amino acid molecules which increase the osmotic pressure of the tissues (which depends on the number of molecules and not on their size), so that water is retained. This is very obvious in urticaria and angeio-neurotic œdema. HCl will be required to neutralise the free amino groups (and presumably NaOH to neutralise the $-\text{COOH}$ groups), so that not only will chloride be retained, but even the corpuscles will give up part of their store.

Hay fever occurs to a preponderating extent in the months of May, June and July, because dry grass pollen, which is the toxic agent, is plentiful at this time; but attacks can be produced artificially in susceptible individuals by dried pollen at any time in the year. It is found that hay fever patients react in varying degree to pollens of different plants; but in this country grass pollen is the only important agent; in the summer there is plenty of it, and it can be carried long distances by wind. In America the pollen of certain *Compositæ* may also cause trouble. The pollen normally produces its effect on the nasal and bronchial mucous membrane after inhalation. If experimentally swallowed by the patient it causes indigestion and diarrhœa.

Asthma. The animal asthmas form another type of toxic idiopathy. Here the patient may be sensitised to the dandruff of a horse, and gets an attack of asthma if horses are in the neighbourhood, or even if he is in the company of ostlers; in such individuals gastro-intestinal attacks have been described after eating sausages containing horse meat. "Cat" asthma is well known; and there is sensitiveness to sheep, cows, pigs, rabbits, goats, and the feathers of birds, so that an attack may start as the result of sleeping on an ordinary pillow. In Holland it has been found recently that grain infected with mites, much used for feeding animals, is a potent source of asthma.

Sensitiveness to foodstuffs is another toxic idiopathy, and eating the specific foodstuff may cause asthma or gastro-intestinal disturbances. Asthmatic patients can be tested by inoculation with the proteins of different foods. Positive skin reactions have been obtained with cereals, such as wheat, maize, rice, rye, barley or oats. Eggs, potatoes, casein, lobster, oyster and various kinds of fish, meat of different kinds, spinach, strawberries, apples, and other vegetables and fruit, have all produced positive reactions in different cases.

There are two methods of testing for "skin reactions" in allergic patients. (1) By scarification; a drop of N/10 or N/20 solution of NaOH is put on the skin of the forearm after cleaning it, and a small quantity of the protein in powder form is applied on the point of a small knife and dissolved in the liquid, and then a superficial cut one-eighth of an inch long is made through the mixture. A positive result appears in twenty to thirty minutes, consisting of an urticarial wheal half a centimetre in diameter with a surrounding zone of erythema. Results

even less than this are recorded, as they may point to the ætiological factor. The control, of course, must be completely negative. (2) By intracutaneous injection; 0.05 c.c. of the required solution is injected into the skin by means of a very fine needle held nearly parallel to the surface. A small button of fluid must be seen, and a control injection with normal saline should be carried out. The front of the forearm is the best place to choose. An inflammatory areola indicates a positive reaction. The intracutaneous reaction is much the most sensitive of the two, and positive reactions have been obtained with various protein extracts (animals' hairs, foodstuffs, pollens) in a proportion of asthmatics, which varies in different countries, but is not large in England.

In the great majority of asthma cases the poisonous substance is unknown. It appears to be air-borne, and in some cases may be a mould. The dust from the house of an asthmatic patient often contains it. It is present in one locality more than another. Thus, in Zeeland there are villages in which 1 per cent. of the population suffers from asthma, and these individuals lose their asthma when journeying up the Rhine. Again, most asthmatics avoid attacks altogether in mountainous regions such as the Alps, though by living there for a time they lose such immunity as they have obtained lower down, and when they return home their attacks may at first be more severe than usual. The freedom from attacks in the Alps is due to the absence of the poison, and attacks may be artificially produced by making the patient inhale dust, etc., specially brought there (15).

In predisposed individuals there are several factors that may actually cause an attack,—irritation of the nasal mucous membrane, constipation, uterine troubles, distension of the stomach with food, over smoking and the dyspepsia that often accompanies it, milk foods, the lead present in hair wash, and even the smell of paint, and especially various psychic conditions. Attacks may occur because the patient expects that they will. Thus a patient sensitised to roses had an attack on seeing an artificial rose which was thought to be real. On the other hand, violent excitement may arrest an attack completely. Attacks are more liable to come on when patients are fatigued, *i.e.* towards the end of the day.

Asthma—Infective and Reflex. This group of cases, which includes the majority of asthmatics in this country, appears to differ from the group just described, though there is overlapping. The asthma often begins at puberty or the climacteric. The immediate precursor may be acute bronchitis or pneumonia, such as may occur in whooping-cough or measles, or the asthma may be due to infection in other parts of the body. The asthma may be due to (1) sensitisation to substances which gain access to the body at the actual site of the infection in the lungs or elsewhere, or (2) to reflex irritation. (1) There is evidence particularly in adults that Gram-negative bacilli of the Friedlander group produce histamine-like substances on culture, and these substances produced locally in the bronchi may be responsible for the attacks (48). Focal infection is dealt with below. (2) That reflex asthma may arise from the nose is quite easy to understand from Brodie's and Dixon's work, which definitely proved that stimulating the nasal mucous membrane produces a reflex bronchial constriction. In fact, asthma has occasionally followed the removal of nasal polypi and other extensive operations on the nose.

The focal infection in this group may be situated in the maxillary antrum; there may be ethmoiditis, nasal polypi, septal deviation, ridges, or spurs, hypertrophy of the turbinates, all tending to obstruct the airway and to favour infection. Tonsils and adenoids do, in a small number of cases, play an important rôle. Certainly the usual history is that these have been operated upon at least once without relief. However, after other avenues have been explored, operation may be called for. The teeth and intestines are other possible sources. There still remain some patients whose asthma starts or is associated with "colds in the head," in whom no cause is demonstrable other than an apparent lack of resistance in the nasal mucous membrane. They are always worse in the winter

months, or rather in the late autumn and early spring, when the weather is most capricious, and the changes sudden and disturbing. Cases of infective and reflex asthma met with in this country do not usually react when tested with proteins like some of the cases of the previous group.

Asthma and Bronchitis. The relation of asthma to bronchitis is three-fold. In the first place, as just described, asthma commonly follows a *primary* bronchitis. In the second place a condition of asthma may gradually supervene when a patient suffers from recurrent attacks of bronchitis, and the asthma may only come on when the bronchitis is at its worst and clear up again when the bronchitis is better. This condition is known as *asthmatic bronchitis* and is not allergic at all. It results because the bronchial inflammation irritates the nerve endings in the mucous membrane, so as to produce a reflex local contraction of the muscles. Asthma also occurs with phthisis. In the third place, repeated attacks of true allergic asthma may lead to a *secondary* chronic bronchitis, as described later in the symptomatology.

Breathless Attacks in Elderly Subjects. This condition is described on p. 255, and is sometimes known as *cardiac asthma*, or as *renal asthma* if the kidneys are affected, as in *arteriosclerotic kidney*. *Uræmic asthma* is sometimes applied to breathlessness in uræmia.

Symptoms. In *hay fever* there are acute rhinitis and conjunctivitis with œdema of the mucous membrane, lachrymation and sneezing; in thin-skinned people there are erythema, urticaria, with severe itching. There may be asthma and constitutional effects such as lassitude, mental depression, irritability and headaches. Paroxysmal rhinorrhœa, in which the patient suddenly has a profuse watery discharge from the nose, is probably allied to hay fever.

Asthma. Sometimes there are *premonitory* indications, such as a general sense of discomfort, drowsiness, gaping, itching under the chin, sneezing and coryza, or the passage of much pale limpid urine. But the attack is often quite sudden, commencing in the early morning between two and four o'clock, though the patient may have gone to bed apparently quite well. He wakes up with a sense of dyspnoea, so that he has to sit up in bed, or gets out and opens the window to let in more air. The breathing is soon so difficult that he has to call in the aid of all the accessory muscles of respiration; he grasps with his hands the sides of his bed, the arms of a chair, the mantelpiece, or the edge of a table, to give a firm support for the muscles which pass from the upper extremities to the chest. At first the chest is nearly fixed in a condition of inspiration, and there is very slight movement, and practically no breath sounds are heard on auscultation; later, when the movements are beginning to get somewhat more free, the most noticeable feature is the extraordinary length of expiration, which is accompanied with a loud wheezing, audible at a distance, while the respiration rate is slow. The chest is somewhat over-resonant; the inspiratory murmur is scarcely audible, or accompanied with a little sibilant rhonchus, while with expiration is heard the loud rhonchus just mentioned. With this the patient's distress is very great; the face gets cyanosed, the eyes are prominent, the conjunctivæ suffused and the whole attention of the patient is absorbed in the attempt to expel the air from the chest. Usually there is no pyrexia. After a time—it may be two or three hours—he begins to cough, and expectorates some thin, transparent mucus, which may be mixed with a little blood; then the breathing becomes easier, the cyanosis is less, gradually the whole trouble subsides, and the patient falls asleep.

The sputum often contains, besides cylindrical or ciliated epithelium, bodies known as Curschmann's spirals. These are yellowish-green or grey particles, made up of threads of mucus. Under the microscope they are seen to be spirally twisted fine or coarse fibres mixed with eosinophil leucocytes, and there is often in the middle one transparent fibre; they are probably formed in the finer bronchial tubes. Two kinds of crystals are also often found, viz., cubic crystals consisting of calcium carbonate (17) and elongated hexahedral crystals known as

Charcot-Leyden crystals, which consist of calcium phosphate and are sometimes found in the spirals. The eosinophil leucocytes of the blood are increased in number.

Each attack of asthma may last from two or three hours to as many days ; their recurrence, at longer or shorter intervals, is a good deal determined by the exciting causes—that is, a careful patient, who knows how to avoid what will bring on his attacks, may escape for long periods. The duration of the illness is also very variable. Many of those who have it in childhood recover in adult age. The attacks themselves are rarely fatal, and the occasional occurrence of not very severe attacks is not prejudicial to health ; but frequent paroxysms induce emphysema of the lungs, and ultimately attendant bronchitis, so that there is constantly more or less lividity, with the round shoulders, barrel-shaped chest, and laboured respiration which are observed in the midst of the paroxysms themselves. Life is thereby shortened, and the tendency to suffer from the severer forms of bronchitis is increased.

Diagnosis. The diagnosis of *hay fever* will be helped by remembering that it occurs in the first half of the summer. The diagnosis in the case of *asthma* is easy, if the history and the character of the breathing and its onset be carefully studied. Sudden attacks of dyspnoea in cardiac disease, thoracic aneurysm, and laryngeal obstruction are those which are likely to resemble asthma most closely. Hysterical attacks may also simulate it. The skin reactions are widely used to determine whether the patient is sensitive to a particular foreign protein. It is very important to make this test for horse serum before injecting antitoxic serum as many asthmatics have died from this. Asthma may be due to organic disease, and *bronchoscopy* will be useful in determining this.

Prevention. In both hay fever and asthma prevention of the attacks is the main object of treatment. In *hay fever* residence in the country during the hay-time should be avoided ; if the sufferer goes out, he may wear a veil over the eyes or nose. Susceptibility to hay fever is said to be diminished by the internal use of calcium lactate. Stimulation of certain spots on the turbinates by lightly touching with the electric cautery after cocainisation has been used.

Much work has been done on the lines of vaccine therapy (18). Alleviation of symptoms and reduction of sensitiveness may be effected in most cases by the subcutaneous injection of dilute extracts of the pollen to which the person is sensitive. An aqueous solution of 1 part in 1,000,000 has been taken as one unit, 1 part in 500,000 as two units, 1 part in 100,000 as ten units, and so on. Preferably two or three weeks before the expected attack 1 c.c. of a very weak solution is injected, and increasing doses, or rather the same dose, 1 c.c., of solutions of increasing strength, are injected every three or four days until twelve or more doses have been given. Freeman tests the sensitiveness of the individual by ascertaining the strength of solution in units which will give the ophthalmic reaction, and checks his later doses by the same test. A solution of 1 in 1,000 appears to be the maximum strength that is advisable.

As regards *asthma*, the most important thing is to keep in as perfect a state of health as possible. In particular, overwork is to be avoided. Regular exercise and adequate holidays should be taken. Some people can live in London and large cities free from paroxysms who have them at once if they attempt to live in the country. Conversely others can only live in the country, and have asthmatic attacks in town. In the same way sea air may excite attacks in some and cure others. The facts with regard to any patient can only be ascertained by experiment. Patients usually do better on high ground.

Moderation and care in diet are the next points to consider. Food should be light and easily digestible ; a heavy supper should not be taken ; and particular food should be excluded from time to time, such as cheese, pastry, pork, beer, to see if there is any one offender in this respect. Toasted bread and well-baked biscuits should be taken. Farinaceous foods should be boiled in water and not

milk; other milk foods, such as Benger's, should be avoided. An ounce of dextrose three times a day may be prescribed with lemon or orange to help the liver. When the patient is fat a low calorie diet is indicated. If it is found that a patient is sensitised to a particular protein, that substance should be avoided, or if this is difficult, desensitisation with the specific protein may be carried out. A capoc pillow is prescribed for patients reacting to feathers. Good results have been obtained by means of non-specific protein therapy. Weekly subcutaneous injections of 1 c.c. of a 1 in 100,000 Koch's T.D.A. tuberculin have been used (19). Peptone injections in the form of a 5 per cent. solution of Armour's No. 2 peptone are injected twice weekly intramuscularly or intravenously. The first dose is 0.3 c.c. and this is gradually increased by 0.2 c.c., the maximum dose being 2 or 2.5 c.c. The maximum dose is that which just fails to give a reaction, and the temperature should be taken four or five hours after the injection to see whether it is raised (20). Peptone (0.5 gram) by mouth exactly three-quarters of an hour before every meal is sometimes successful. Injections of the patient's own proteose prepared from the urine have been tried with varying success. Other methods of the most diverse kind may be described which perhaps act by causing some general reaction which temporarily desensitises the patient. A hot bath, with the temperature rising from 98° to 106° F., of twenty minutes duration before going to bed may ward off nocturnal attacks. An "erythema dose" of ultra-violet light on an area of skin or an exposure to X-rays may act in the same way (21). Exposure to a hot, moist atmosphere is used at Mont Dore. Lightly stroking the nasal septum with the electric cautery will sometimes stop attacks, and this is of most value when the nose is free from deformity and polypi and the systolic blood pressure is on the high side (120 to 160 mm.). In no circumstances should polypi be removed in asthma (16). Airtight chambers have been constructed in which the patient sleeps. They are ventilated by air drawn from a height of 100 feet, which may be further purified from moulds by refrigeration. It is suggested that the patient remains free from attacks because for a large part of the twenty-four hours he is protected from these atmospheric substances (22). Liquor arsenicalis in 5 mm. doses, bromides, and particularly potassium iodide in doses up to 30 gr. a day are the most valuable drugs to prevent the onset of attacks. Mild purgation with calomel in small doses is also of value, and salol and other intestinal disinfectants have been used.

When asthma is associated with infection other additional methods are available. Coryza should be treated with the paraffin and vaseline mixture described on p. 196. Autogenous vaccines may be prepared from the sputum or nasal secretions, or a stock vaccine may be used. They are best given *intracutaneously*, and the amount of the local reaction is a guide to the dose. Septic foci should be looked for and dealt with.

Treatment. For *hay fever* Morell Mackenzie recommended a spray of a 4 to 6 per cent. solution of cocaine to the eyes and nose. In the case of the nose this was followed by the daily introduction along the floor of the nose of a bougie, smeared with vaseline or oil, and left in for ten minutes at first, and for gradually increasing periods up to half an hour or longer. Adrenin hydrochloride may be sprayed into nose or throat from a solution of 1 to 5,000. Where there is chronic hypertrophic rhinitis, the application of the galvano-cautery to the swollen mucous membrane, after the preliminary use of a 2 per cent. solution of cocaine, seems to be quickly curative.

To stop an attack of *asthma* an injection of 1 to 2 minims of 1 in 1,000 adrenin hydrochloride is the most certain treatment, though 10 and even 15 mm. have been injected intramuscularly. A convenient method of administration is by a spray of 1 in 1,000 adrenaline containing 10 per cent. glycerine, 0.5 per cent. chloretone and 2 drops of sulphurous acid per oz. The spray may be worked by hand or by a pump, or oxygen from a cylinder may be used as the motive force. Synthetic crystallised adrenine (1 mgm.) may be absorbed by keeping it under

the tongue. Caffeine iodide ($7\frac{1}{2}$ gr.) or pyramidon ($4\frac{1}{2}$ gr.) and ephedrin ($\frac{1}{2}$ gr.) may be taken by mouth. Amyl nitrite is also commonly inhaled, or maximal pharmacopœial doses of Tr. lobeliæ aeth., Tr. stramonii, Tr. belladonnæ, chloral hydrate, the nitrites, or nitroglycerine may be given by mouth. A very common method of treatment is to inhale the fumes from burning a paper saturated with nitre solution and dried, or to smoke cigarettes made of chopped stramonium leaves, or to use other preparations containing stramonium. Inhalation is a bad method of regular treatment, because the bronchial mucous membrane is irritated, with resulting bronchitis.

Status asthmaticus has been averted by treating the patient with oxygen and carbon dioxide in an oxygen tent (49). The author has arrested some attacks by increasing the intra-pulmonary pressure (see Pulmonary Œdema). The oxygen tent without CO₂ causes relief if there is much bronchitis.

OBSTRUCTION OF THE LARGE BRONCHI

In their relation to the various causes of compression, the two main bronchi closely resemble the trachea, and much that has been said under the head of tracheal obstruction might be repeated here. Obstruction, due either to compression or stricture, may result from pulmonary carcinoma, aneurysm, foreign bodies and bronchial glands enlarged by malignant growth or by caseation and suppuration; less commonly epithelioma of the œsophagus, gumma, and even a dilated left auricle may press upon the bronchus. The special liability of the left bronchus to compression by an aneurysm of the arch of the aorta, under which it passes, is of importance. Foreign bodies more frequently fall into the right bronchus, because it is the larger; and the dividing ridge between the two bronchi is somewhat to the left of the middle line, and hence objects falling down the centre of the trachea are directed into its right branch. They may be driven into the trachea during coughing, and fall back into the same or the opposite bronchus.

The obstruction of a bronchus is followed by important changes in the corresponding portion of the lung, and the distal divisions of the bronchus. Ultimately in every case the *lung becomes collapsed*, because, when the interchange of air completely ceases, what remains is absorbed by the pulmonary vessels; ultimately there is pulmonary fibrosis. In a rapidly complete obstruction, as from impaction of a foreign body, this collapse occurs very early; but when the compression takes place slowly, as in the case of an aneurysmal sac, there is at first *distension* of the lung with air, such that the heart may be pushed out of place, and the diaphragm forced downwards (Newton Pitt). A loose foreign body, acting like a ball and socket valve, produces a similar effect.

Another result is *bronchiectasis*, which may develop in the course of two or three months. The most serious inflammation is to be expected quite early when the foreign body is a pea-nut. Other complications caused by foreign bodies are abscess, and occasionally pneumothorax or pyo-pneumothorax in acute cases, and empyema or profuse hæmoptysis in long-established cases (23).

Symptoms and Physical Signs. These vary with the degree of obstruction and rapidity of its production; and since the opposite tube is often free, and thus only half the respiratory area is interfered with, the bronchus is often much more completely obstructed, before death occurs, than ever the trachea can be.

Dyspnœa at rest or on exertion is the only constant symptom at first, and occasionally there are stridor and slight hæmoptysis; but obstruction of either main bronchus may lead to the same paroxysms of asphyxia as occur in tracheal obstruction. When bronchiectasis has developed, cough, expectoration of offensive sputum, and febrile reaction become prominent symptoms.

The chief physical sign is the absence or extreme weakness of the vesicular murmur, which is in strong contrast with the increased breath sounds on the opposite side. This, in some cases for a time, may be the only physical sign, for the resonance may be perfectly normal. But in the cases in which distension of the lung takes place there will be hyper-resonance on percussion, with extension of resonance over the cardiac area and evidence of displacement of the heart, so that the resemblance to pneumothorax may be very close. In these cases eventually, and in other cases much sooner, as the air becomes absorbed, there is dulness at the affected base, with diminished tactile vibration. This may go on to complete absence of breath sounds, voice sounds, tactile vibration, and percussion resonance. If considerable bronchiectatic cavities should be formed, the above physical signs may be, over one or other small area, replaced by tympanitic percussion note, cavernous breathing, crackling, gurgling râles, bronchophony and pectoriloquy.

Diagnosis. The combination of good resonance with nearly complete absence of respiratory sounds on one side of the chest is very characteristic of obstruction of the corresponding bronchus. When the obstruction is accompanied by stridor, it may be mistaken for bronchitis. Stridor from the above cause is persistent and uniform in character, arising from a single point of obstruction, whereas the rhonchi of bronchitis vary constantly in loudness, pitch, and position.

In compression of the bronchus with a distended lung, pneumothorax has been wrongly diagnosed on account of the hyper-resonance with absence of breath sounds. In these cases a radiogram may show the presence of aneurysm in the case of compression, or the lung retracted towards the spine in the case of pneumothorax.

When, on the other hand, the stenosis causes, as eventually it must do, more or less complete collapse of the lung, the physical signs resemble those due to a partially absorbed pleuritic effusion, and the exploring syringe may be necessary for a final decision.

Where foreign bodies are in question, the history must, of course, be carefully considered. Many are opaque to the X-rays. In suitable cases the *bronchoscope* may be employed.

Prognosis. This depends on the nature of the obstruction and the degree of inflammatory reaction. The lung may become extremely tolerant to a foreign body, as is shown by the fact that cases have lasted for thirty-six years, with persistent bronchiectasis and fibrosis of the lung (23).

Treatment is similar to that of obstruction of the trachea.

EMPHYSEMA OF THE LUNGS

The term *emphysema* (from ἐν, in, and φῶσα, wind) is rightly used to denote the extravasation of air into the subcutaneous or other tissues of the body (*surgical emphysema*), and into the interlobular or interstitial tissue of the lungs (*interstitial emphysema*). It is much less applicable to the disease of the lung now under consideration, for which, however, in medical parlance it is usually reserved. The alveoli of the lung naturally contain air; in this disease they are abnormally distended, and may be said to contain too much. So far the name *emphysema* (*vesicular emphysema*) may be justifiable; but the name *alveolar ectasis*, which has been suggested, is more correct.

Ætiology and Pathology. Several factors are concerned in the production of emphysema. Some of these operate in chronic bronchitis, one of the commonest causes of the condition. (1) Just before the action of coughing there is a high pressure in the lungs behind a closed glottis. This interferes with the blood supply, since the pulmonary blood pressure is low, so that, in course of time,

degeneration of the lung tissue takes place. (2) At the end of coughing a deep inspiration is taken, causing distension of the alveoli, stretching of their walls, and narrowing of the capillaries, with interference with the blood supply again. (3) The force exerted by the muscles during inspiration is greater than during expiration, because the latter action is largely due to the elastic recoil of the lungs. Where the bronchi are partially obstructed with secretion, air may be drawn into the alveoli against the obstruction during inspiration, but cannot get out again during expiration, so that the alveoli are permanently distended. This is the factor that operates in asthma, the obstruction being due to contraction of the bronchial muscles. The obstruction acts as a valve, allowing air to enter, but not to come out again. (4) Prolonged stretching of the alveolar walls has been thought to occur in glass-blowers, and in players of wind instruments, and in those engaged in laborious occupations, who are continually keeping their chests expanded, either to supply a slow regulated stream of air or to serve as a *point d'appui* for the use of the arms. Recent observation makes this doubtful (24). (5) In the course of years the elastic tissue of the lungs gradually wears out, producing the *small-lunged emphysema* of elderly people. (6) When a portion of the lung shrinks from disease or becomes infiltrated with inflammatory products or a neoplasm, it cannot expand during inspiration. Consequently the expansion of neighbouring alveoli must be increased so as to fill up the vacant space. This is known as *compensatory emphysema*. By such various means do the septa between adjacent alveoli become atrophied in emphysema. Soon a perforation is established through the septum; then the whole septum is destroyed, and the two alveoli become one. In this process not only the elastic tissue, but also the whole network of pulmonary capillaries contained in the septum, disappear. If this is repeated extensively throughout the lungs, first, all the air spaces are much enlarged, and in many places great blebs of lung tissue simply containing air are formed; secondly, the elasticity of the lung necessary for expiration is reduced much below the normal; thirdly, the vascular area available for aerating the blood is greatly diminished; and fourthly, in most cases the lungs themselves are considerably enlarged.

In consequence of the loss of elasticity, expiration becomes more difficult. Parallel with the increase in size of the lungs, the chest enlarges in width and depth, assuming permanently the shape and position which are characteristic of full inspiration; the mobility of the chest is much diminished, since it ranges only between different degrees of inspiration, instead of between full inspiration and full expiration. The interchange of gases is less complete. This is shown by the values found for the pressure of CO_2 in the arterial blood, which are much above the normal. There is, in fact, a CO_2 acidæmia, which causes severe dyspnoea. The saturation of the arterial blood with oxygen may also be below normal (7); there is commonly an increase in the alkali reserve, which tends to compensate for the CO_2 retention.

Another important factor is the *loss of capillary area* in the lungs. From this there results an obstruction to the pulmonary circulation. The tension in the pulmonary artery and right ventricle is increased, the right ventricle hypertrophies, and later there is dilatation of the right side of the heart, so that the venous system becomes engorged, producing congestion and enlargement of the liver, œdema of the feet, legs, and trunk, and albuminuria. In elderly people there is usually also left-sided dilatation of the heart with myocardial degeneration.

Morbid Anatomy. A lung affected with *large-lunged emphysema* does not collapse when the chest is opened at the post-mortem examination, but even bulges out through the aperture. It is soft and inelastic, and yields to the pressure of the finger ("pitting"). In different parts of it, especially along the inner and lower edges, may be seen large blebs the size of peas or nuts; and the lung is unusually pale and bloodless, and of a mottled grey colour. On section the large

blebs collapse ; and the whole organ is much drier than usual, except in some parts, such as the bases, which may have been the seat of a complicating bronchitis or œdema.

A second variety (*small-lunged emphysema*) occurs in old people as a senile atrophic change ; the lung is not enlarged, and blebs are not numerous. The septa have atrophied so that alveoli have joined together, and the lung is shrunk, inelastic, dry, and pale, and presents a less perfectly spongy structure than normal.

The greater development of emphysema in certain parts of the lungs, specially the apices, anterior margins and lower edges, may be accounted for on Jenner's view—that when air is retained in the chest under great pressure, as when coughing or making any great muscular effort, it is the parts of the lung which are least supported by the surrounding structures which will bulge out owing to the air pressure from within.

Symptoms and Physical Signs. The symptoms of emphysema are at first only shortness of breath ; the cough and expectoration which are commonly present result from a co-existing bronchitis. The dyspnoea is especially seen on exertion in early stages, when the breathing is quickened and the patient readily pants ; later on it may be always present, producing orthopnoea at night. In its worst forms the extraordinary muscles of respiration are in constant use ; the clavicles are lifted ; and the sterno-mastoids and scaleni stand out at each inspiration, striving to increase the tidal air ; expiration is prolonged, laboured, and aided to their utmost by the muscles of the abdomen. The *physical signs* are characteristic. The chest is broad, deep antero-posteriorly, but short ; it is often called barrel-shaped, from its enlargement, and from the increase of the antero-posterior diameter giving it rather a circular than a transversely oval shape. The shoulders are raised ; the upper ribs are closer together, and the lower ribs wider apart than normal ; and the epigastric angle is very obtuse, measuring 105° or more. The elevation of the ribs alters the relative positions of the nipple and the heart's impulse ; the nipple is often found on the fifth rib, and the heart's impulse in the sixth space. Percussion gives excessive resonance over the parts of the chest which are normally resonant, and an extension of the resonance over areas which are normally dull. Thus the hepatic and cardiac dulnesses are encroached upon, the right lung being resonant down to the sixth space or seventh rib, and the superficial heart dulness often disappears altogether. On auscultation the breath sounds are very much diminished or scarcely audible, but the expiratory murmur may be much prolonged when there is coincident bronchial spasm, and rhonchi may be audible.

The enlargement of the lungs also affects the signs connected with other organs. Since a larger portion of lung than is normal lies between the heart and the chest wall, the impulse of the heart may be imperceptible in the fifth space, the cardiac sounds are faint, and the fact of dilatation or hypertrophy may be concealed.

In small-lunged emphysema the chest is more nearly circular in its outline, but it is not enlarged ; the lungs do not cover the heart ; and the heart is not hypertrophied, but atrophied. The percussion note is hyper-resonant, and the inspiratory murmur is feeble, but the expiration is not prolonged.

In both forms the rhonchi of bronchitis are frequently present ; in extreme cases there are râles at the bases of the lungs, with an impaired note due to œdema.

Complications. Chronic bronchitis is frequently present, with or without bronchiectasis. In elderly people there is commonly myocardial degeneration with hypertrophy and dilatation of the left side, as well as of the right side, of the heart, and there may be general œdema. There is often arterial degeneration associated with senile arteriosclerotic kidneys. This type of case is more fully considered on p. 255.

Diagnosis. Its recognition depends upon the altered quality of resonance,

and especially upon the extension of resonance over the præcordial area, and downwards over the liver. In the small-lunged variety the altered quality of resonance and the dyspnoea are the chief features. The Röntgen rays show a more extensive and lighter area over the lungs than in health, and a lower position and less extensive movements of the diaphragm.

Prognosis. Actual recovery does not occur, only relief of symptoms. The duration of life depends upon the extent of the change, the liability to bronchitis, and the state of the cardiac muscle. In most cases the final result does not come under several years.

Treatment. This must be directed to improving the general health of the patient, to avoiding all risk of bronchitic complications, and to relieving these when they occur. Thus the patient should have nutritious and digestible diet, should be well clothed, live in warm, well-ventilated rooms, and avoid east winds and the night air. Tonics, such as cod-liver oil, iron, strychnia, and quinine, are used. Attempts have been made to compensate for the loss of elastic tissue. Thus Gerhardt advises assisting expiration by mechanical compression of the thorax; this is done by another person with the hands upon the lower part of the thorax for five or ten minutes every day. The accompanying bronchitis should be treated. The treatment by compressed air, as in the steel chamber at the Brompton Hospital, depends on the increase in the concentration of oxygen in the inspired air, and this has been found of value in emphysema, particularly if there is bronchitis. An oxygen tent can also be used.

COLLAPSE OF THE LUNGS

(*Atelectasis Pulmonum*)

A distinction is often made between lungs that have never completely expanded (atelectasis) and those that have after expansion partly returned to the foetal state (collapse). *Atelectasis* is congenital, and is seen in very weakly children, whose respiratory movements are insufficient to draw in the required amount of air. It occurs the more readily because the lungs after removal from the body at birth are about the same size as the chest cavity, and so there is not the same suction power, compelling the entry of air, as there is in later life, when the lungs are smaller than the chest cavity. *Collapse* is an acquired condition due to failure of air to enter the lungs, and results from (1) obstruction to the entrance of air by the air passages, (2) compression of the lung from without. It is not due to paralysis of the diaphragm, since it never occurs after phrenic avulsion.

(1) *Obstruction* may arise from chronic enlargement of the tonsils, adenoid growths in the naso-pharynx, much more often from the viscid, mucous, or purulent secretion of bronchitis, especially in children, and as a part of broncho-pneumonia, and in older people from constriction of the bronchus by neoplasm or by aneurysm or some other of the causes previously mentioned.

(2) The causes of *compression* are numerous: in the chest itself it is most frequently due to pleural effusion, but also to enlargement of the heart, pericardial effusion, mediastinal tumours, aneurysms of the aorta, and angular curvature of the spine (kypho-scoliosis); in the abdomen, to the pressure of tumours growing from the upper surface of the liver, especially hydatids, abscess and neoplasm, of sub-diaphragmatic abscesses, hydatid of the spleen, ascitic fluid, and ovarian tumours.

(3) In wounds of the chest and sometimes other parts of the body, a *massive* collapse of the whole of one lung may occur. There is no necessity for the wound to penetrate into the chest cavity, and the lung opposite to the side of the wound may be affected. The condition may or may not be associated with hæmo-thorax. *Massive* collapse occurs not uncommonly after operation for acute abdominal conditions. It is now considered to be due to blocking of the tubes

by inflammatory products, the pneumococcus, Type IV., being mainly responsible (49). Consequently the air is absorbed from the alveoli, and so collapse occurs.

Morbid Anatomy. Lung in a state of collapse or atelectasis has a violet or dark purple-grey colour, and is tough, airless, and dry on section. Isolated patches are seen to be slightly depressed below the general surface. Unless subsequently the seat of inflammation, they may be again expanded by forcible inflation with air.

Symptoms. In congenital atelectasis the child is weakly, more or less livid, with rapid shallow breathing and feeble cry. With each inspiration the lower part of the chest is drawn in, and the intercostal spaces are depressed. Examination may elicit a little loss of resonance at the bases, and occasionally some râles, but feebleness of breath sounds is the chief physical sign. The collapse of bronchitis is rarely extensive enough to reveal itself by auscultation, its distribution being lobular and scattered.

When collapse is more extensive and uniform different stages can be recognised by the physical signs. A very slight degree of collapse may occur at the bases from temporary disuse of the lung as a result of early pleurisy, or from prolonged dorsal decubitus. When the affected area of lung is auscultated, the breath sound is very feeble; if the patient breathes deeply, there is a louder vesicular murmur, and at the end of it fine crepitations, which are due to the fresh expansion of hitherto collapsed air vesicles.

The physical signs of collapse due to obstruction of a bronchus have just been considered. In the case of compression by fluid, etc., the early signs may be dulness, diminished tactile vibration, and either diminished or faintly bronchial breath sounds. When complete they are absolute dulness, absence of breath sounds and tactile vibration.

In the massive collapse associated with retraction of the chest wall due to wounds, there is dulness, and there may be deficient breath sounds and absent tactile vibration, but in advanced cases there may be instead loud bronchial breathing and increased tactile vibration. The chest wall is retracted, the intercostal spaces depressed, the diaphragm raised and immobile, and the heart drawn over to the affected side. When a hæmothorax is present on the affected side, although the chest wall is retracted, the heart may be pushed over towards the sound side. This occurrence is strongly in favour of the primary cause being paralysis of the chest wall, because in the last case this persists even though the pressure in the chest on the same side is increased by the hæmothorax. Massive collapse after operations is commoner than is generally supposed. Probably the cases are often diagnosed as pneumonia owing to the physical signs.

The symptoms are dyspnœa, which, however, may be slight when the patient is at rest, cyanosis, and sometimes pain.

Treatment. Oxygen, with or without CO₂ as a respiratory stimulant, is the correct treatment for massive collapse and in atelectasis of the new-born good results are obtained, though some method of artificial respiration may also be required (49). Elliott and Dingley recommend that expectorant medicines with potassium iodide should be given, that all abdominal bandages should be loosened as far as possible, and that the patient should be encouraged to make full inspiratory efforts, especially of an abdominal type, for five minutes every hour. Bronchial obstruction may be removed by bronchoscopy.

ŒDEMA OF THE LUNGS

Ætiology. Some degree of œdema of the lungs is found in the majority of post mortems, especially where the patient has been lying for some time in bed before death. For this reason it is most marked at the base and along the

posterior borders of the lungs (hypostatic œdema). Certain diseases are particularly likely to cause it; these are myocardial disease and especially aortic regurgitation, where it may come on acutely owing to rapid failure of the left ventricle, while the right ventricle goes on pumping blood into the lungs; hydræmic nephritis; an inflammatory œdema generally accompanies acute pneumonic processes. Suffocative poison gases produce œdema of the lungs.

Morbid Anatomy. A lung affected with œdema is bulky, heavy, and exudes when incised an immense quantity of serous slightly blood-stained frothy fluid.

Symptoms. The chest may be at first resonant, but later shows some impairment of the note at the bases behind; here the breath sounds are deficient, and there are heard only abundant fine and medium râles. In the acute form (*acute suffocative œdema*) the patient is taken suddenly with expiratory dyspnoea and orthopnoea or rattling respiration, which may be a protective mechanism; the inspirations are made as short as possible as the lowering of pressure would help œdema formation. On the other hand prolonged expiration against resistance from contracted bronchioles (asthmatic breathing) increases the pressure in the lungs; this principle is made use of in treatment. Other symptoms are restlessness, sense of suffocation, more or less cyanosis, small rapid pulse, and expectoration of large quantities of colourless or blood-stained, frothy, watery fluid. This may be quickly fatal, or subside in the course of a few hours. There may, however, be no expectoration until some days have elapsed, and, indeed, none at all, in some quickly fatal cases. In the final œdema of pneumonia, the râles are audible over the whole of the hitherto healthy lung. It has only recently been recognised from experimental evidence that the nocturnal breathless attacks or paroxysmal dyspnoea of elderly subjects (*q.v.*) are sometimes due to acute pulmonary œdema (49).

Diagnosis. Acute pulmonary œdema coming on suddenly in a person, who has been carrying on his usual occupation, must be distinguished from coronary thrombosis where the pain is severe, and from pulmonary embolism, in which the expectoration occurs later and contains more blood.

Treatment. When the disease is of circulatory origin the apparatus suggested by Plesch should be used. The principle is to apply a positive pressure to the inside of the lungs so that the over-active right ventricle will be hindered. The air is supplied by a motor fan to a tightly fitting mask and escapes into the outside air through a resistance (49). The author now uses an electrolux blower, and a water manometer attached near the mask indicates the pressure, which should be 3 or 4 inches of water. Remarkably good results have also been obtained with the oxygen tent. In very acute cases venesection may be tried.

PNEUMONIA

Inflammation of the substance of the lung, as opposed to the bronchial tubes, is called pneumonia. As an *acute* disease it leads to consolidation by exudation into the air vesicles of inflammatory products, which are usually absorbed in the course of recovery. In a *chronic* form it causes a dense fibrous transformation of the interstitial tissue, which is permanent. Of acute pneumonia two typical forms can be distinguished from one another by the following features: *Lobar pneumonia* occurs at all ages, but more often in adults, affects large portions of the lung at the same time, and has all the characteristics of a specific infectious disease, with a limited duration, a quick recovery, and sometimes epidemic prevalence. *Broncho-pneumonia* affects chiefly infants, children, and elderly persons, invades several small areas of the lung, and is much less definite in its course and modes of onset and termination.

Experimentally, pneumonia has been produced in rabbits by insufflating one

main bronchus with cultures of pneumococci (Types I. and IV.) of varying virulence. When the virulence is low the cocci are taken up or side tracked by those alveolar systems that open directly out of the walls of the larger bronchi, and broncho-pneumonia, with proliferation of the alveolar endothelial cells, results. With higher virulence the cocci increase rapidly and spread out into the lung tissue, producing a lobular pneumonia, and with still higher virulence a lobar pneumonia with polymorphonuclear reaction and occasionally a fatal lymphangitis; while if the dose is too large they may spread through the pleural surface, causing pleurisy with effusion and pericarditis. With the highest virulence of all a rapidly fatal septicæmic invasion takes place and the lungs show only a patchy serous exudate, desquamating alveolar cells and small hæmorrhages, without any polymorphonuclear reaction, similar to the appearances observed in very fatal epidemics in schools. Positive blood cultures are often obtained during the first two or three days, but not later; and it has been found that the cocci are within the leucocytes; only in cases of fatal septicæmia are they free. This suggests that a positive blood culture at the beginning of a specific fever, *e.g.* cerebrospinal fever or typhoid, cannot be taken to prove that the infection is primarily blood born; it may only mean the escape of phagocytes into the blood-stream in the early period when the bacteria are rapidly proliferating in a particular focus, while metastatic foci, such as "rose-spots," are only places where these circulating phagocytes happen to be held up (9). These observations suggest that all pneumonia is the result of infection through the air passages, and this is now generally recognised. Evidence has been brought forward that the primary lesion is due to blocking of the larger bronchi by plugs of sputum, which are more viscous in the case of the pneumococcus than the streptococcus; thus the latter causes a broncho-pneumonia. X-ray shadows in lobar pneumonia (Plate 3) are often wedge-shaped like an infarct; the diaphragm on the affected side is raised; the heart is never displaced to the opposite side. The virulent pneumococci spread peripherally into the lung; but if the non-virulent Type IV. is present there is massive collapse instead of pneumonia. Much experimental evidence has been brought forward in favour of this view (49).

LOBAR PNEUMONIA (PNEUMOCOCCAL)

(*Croupous Pneumonia*)

Ætiology. The disease occurs in both sexes, but it is twice as common in males as it is in females, the difference between the two sexes being least marked in the very young, and in old people. It is seen also at all periods of life from infancy to old age, but it is more frequent in adults up to middle age. It occurs much more often in the winter and spring than in the summer and autumn, when the temperature is undergoing sudden changes, when the winds are east or north-east, or when the weather is wet or cold. Habits and occupations which involve exposure dispose to pneumonia. Intemperate habits also dispose to it, and greatly increase its mortality. One attack does not exempt from another; indeed, pneumonia is said to have occurred as many as fifteen or twenty times in the same patient, but more than two attacks are not very common.

Cold or chill often seems to be a determining event and there is commonly a history of preceding respiratory catarrh. Cases of direct contagion appear to be undoubted; and many instances are recorded in which pneumonia has spread rapidly through villages, large buildings, or households, precisely like an epidemic fever. Lobar pneumonia also occurs as a complication or sequela of some other diseases, such as mitral disease, acute nephritis, and diabetes; but it is rare as a complication of tuberculosis. Traumatic pneumonia sometimes occurs from a blow on the chest, if the injured lung becomes secondarily infected. In

pneumonia the primary seat of infection is the lung; the *pneumococcus* is found in the lungs and sputum, and in severe cases in the blood, possibly due to escape from the lungs; hence this bacteriæmia hardly constitutes *septicæmia*. The four types of the pneumococcus have already been described (*see* p. 56).

Morbid Anatomy. In pneumococcal pneumonia, the part of the lung affected is converted from a spongy structure into a solid mass. In the earliest, or first, stage of *congestion* or *engorgement*, the lung is heavy, reddish brown in colour, exudes a frothy, reddish serum on pressure, and breaks down more readily than in health. The capillaries are dilated and tortuous from distension with blood, and minute hæmorrhages may be present. In the second stage—called *red hepatisation*, from the resemblance which the consolidated lung bears to the liver—the organ is of a dull red colour, finely granular on section, completely airless, solid, sinking in water, but breaking down readily under the pressure of the finger. The contents of the alveoli, which may be detached in fine granular masses, are seen to consist of fibrin, containing some red blood corpuscles and leucocytes. What has actually happened is that the walls of the alveoli have been so distended with fluid exuded from the capillaries that the endothelial cells have given way, and the air spaces have become flooded with fluid that soon coagulates (42). The third stage, *grey hepatisation*, is also characterised by its solidity, but the colour is greyish yellow or simply grey, and the surface is less granular than that of the red stage. Microscopically it differs from the latter in that the air cells and alveolar walls are crowded with leucocytes, while fibrinous exudation and red corpuscles are in very small quantity. The change of colour is attributable to the leucocytes in the alveoli. A fourth stage, that of *purulent infiltration*, is also described; but this is only an extreme condition of grey hepatisation. The lung is softer, yellowish in colour, and yields to scraping or pressure a quantity of yellow purulent fluid, which is provided by the disintegration of the infiltration filling the air cells, the leucocytes becoming fatty and granular. A true *abscess*, however, is exceedingly rare as the result of typical acute pneumonia. It is doubtful whether the stage of purulent infiltration is ever reached in cases that recover; it is true, recovery, or *resolution*, is sometimes accompanied by physical signs (*redux crepitation*) which indicate that the exudation is softening into fluid. But many patients get well without such evidence, and with so little expectoration that the removal of the exudation can only be explained by its absorption directly by the lymphatics; in but few cases the amount of sputum is very considerable.

The inflammation of the substance of the lung is accompanied, in a large proportion of cases, by acute pleurisy, and the double lesion may be spoken of as *pleuro-pneumonia*, but the name is not generally used except for cases in which the pleurisy is clinically a prominent feature.

Localisation. Pneumococcal pneumonia is nearly always partial, affecting the base more often than the apex, and the right lung somewhat more often than the left. X-ray examination usually shows a wedge-shaped shadow of variable size (Plate 3, A, B, C), and this has long been recognised in the case of children (33); occasionally the shadow forms a band in the periphery parallel to the chest wall. Infiltration may be present without physical signs. The shadow may imitate epituberculosis, but it disappears much quicker. Sometimes both lungs are affected, but the disease commonly begins in one earlier than the other.

Symptoms and Physical Signs. *First Stage.* A rigor or shivering (69) occurs, in a large proportion of adult cases, as the first definite sign of illness; the temperature rises to 102°, 103°, or 104°, and there is well-marked pyrexia, with malaise, loss of appetite, vomiting (33), furred tongue, and in some cases an eruption of herpes on the lips (17), which is to be regarded as a favourable sign. Children often have convulsions, but rigors uncommonly. The symptoms may

(The *italic* numbers in brackets refer to percentage incidence of symptoms in 558 cases of lobar pneumonia among soldiers at Aldershot, 1915–17 (25).)

be at first vague, accompanied perhaps with pain in the head (35·6) or pains all over (9), or the implication of the lung may be indicated by shortness of breath and severe pain in the side (60), attributable to pleurisy. Auscultation at this early period may detect nothing, but sometimes there is heard a fine dry crepitation, which has been compared to the noise produced by rubbing between the finger and thumb a lock of hair near the ear; it is mostly heard towards the end of a deep breath, but sometimes during the whole of inspiration; and it is explained by the separation of the walls of the alveoli, rendered unnaturally adhesive. More often the first deviation from the normal is a marked diminution or loss of the vesicular murmur over the area which subsequently gives the signs of the second stage, or consolidation. The percussion note may be still unaltered, or only slightly less resonant than normal. In other cases a tympanitic note is obtained. This is liable to occur when the pneumonic process is central to begin with, so that there is relaxation of the surrounding lung (as in Skodiac resonance).

Even as early as this there may be slight cough, with the characteristic *rusty sputum*. This is brought up as a mass of transparent, airless, jelly-like mucus, of a yellow, orange, russet-brown, or even bright red colour, and extremely viscid, so that it adheres to the side or bottom of the vessel with little or no tendency to flow. The pneumococcus may be detected in the sputum by Gram's method of staining; but it is not at first abundant, and the sputum consists chiefly of hyaline mucus, sero-albuminous exudation, some red corpuscles, small alveolar cells, large endothelial cells, and a few polymorphonuclear cells. Hæmoptysis (1·6) is an occasional feature.

The physical signs of the *second stage*, or stage of consolidation, are often rapidly developed. There is decided dulness over the part of the lung affected. Over the same area there is high-pitched bronchial breathing, at first soft and distant, but in a short time much louder. If the patient speaks, there is bronchophony, the words uttered being often distinctly heard, and apparently shouted up into the stethoscope; whispered words are also distinctly transmitted. The fine crepitation heard as an early sign may still be audible in portions of lung which are being involved by the spreading inflammation; but over areas which give loud bronchial breathing and bronchophony no râles will be heard unless there is associated bronchitis, and then they will be consonating. Tactile vocal fremitus is sometimes increased and sometimes diminished. There is evidence that in nearly all cases the latter is due to a thin layer of fluid in the pleura (26). During this development of the physical signs the patient is necessarily confined to his bed, but he often has orthopnoea; his cheeks and forehead are flushed; his eyes are bright, and show a vivid consciousness of his distress; his breathing is quick, and the respiration may rise to 40, 50, 70, or even 80 in the minute. The pulse is quickened, but not in proportion to the respiration; it may be 100 to 120, or somewhat higher; thus the pulse respiration ratio is altered from the normal 3 : 1 or 4 : 1 to 2 : 1 or $1\frac{1}{2}$: 1. The temperature is maintained generally at a high level, 103° to 105°, with little variation; and the skin is dry, and gives a sense of pungent heat to the hand placed on it. The blood pressure is generally a little below the normal. The cough, which is usually, though not always, present, is not very frequent, is hard, dry, and often painful; and the viscid, rusty sputum is brought up with difficulty. The urine is scanty, high-coloured, acid, and deposits urates; the chlorides are much diminished and may be absent, and there is not infrequently a small quantity of albumin. There is generally leucocytosis with increase in the polymorphonuclear cells, which persists for a long time in severe cases. The patient may become delirious (4), especially at night. Lividity or cyanosis may be a striking feature. It has been found in such cases that the saturation of the arterial blood with oxygen is diminished, being 80 per cent. instead of 95 per cent., which is the normal (Stadie). This desaturation is due to the arterial blood being a mixture of aerated blood from

the healthy part of the lung and non-aerated blood from the diseased lung. Later cyanosis often wears off, when the circulation through the diseased lung is slowed.

The general condition of the patient continues very much the same for some days, or more often there is an increase in the severity of the symptoms. The pulse and respiration are quicker, the temperature continues high, the tongue becomes drier and browner, and the delirium at night is more decided. The physical signs are generally observed to alter from day to day, indicating the spread of the consolidating process, so that crepitation and bronchial breathing extend higher and higher up to the chest, until the apex is involved, and the physical signs may be apparent in front under the clavicle.

When the illness is apparently at its worst, improvement takes place, in many cases quite suddenly. On the sixth, seventh, or eighth day, in a large proportion of cases, the temperature, the pulse, and respiration fall, in the course of twelve or eighteen hours, nearly to their normal limits; the tongue becomes moist; and the patient feels himself in all respects better. This *crisis* (56·4) is accompanied with profuse sweating. In about half the cases the fever ends more gradually (*lysis*), occupying from four to five days while falling from the acme to normal.

The physical signs gradually clear up after the temperature is normal. *Redux crepitations* are heard in this stage. They are rather coarse crackling or bubbling râles, due to the loosening of the exudation and its presence in the tubes. With the change in the lung, the sputum is also altered, losing its characteristic tinge, becoming yellow or green, muco-purulent, and at the same time less viscid.

Type I. pneumonia, which accounts for 30 per cent. of cases, especially in young adults, usually presents the classical symptoms ending by crisis. In Type II. the symptoms are more severe and there is often no crisis. Type III. is particularly liable to attack the elderly. Type IV. occurs at any age. In fatal cases death occurs from failure of the heart, or from œdema of the hitherto unaffected lung, or from both combined. All the symptoms are aggravated—the respirations are increased in frequency; the pulse is quick, small, and feeble; the face becomes livid or cyanosed; the physical signs of dilatation of the right ventricle may be observed; the tongue is dry, brown, and cracked; delirium is more or less continuous, and muttering and coma gradually supervene. On auscultation loud, coarse râles are heard on both sides of the chest. As the patient becomes feebler the temperature falls, the skin becomes cold and is bathed in profuse perspiration. Death commonly takes place during the height of the illness, between the fifth and the tenth days. Occasionally, however, a pneumonia runs a fatal course in two or three days.

Complications and Sequelæ. The former are mostly the result of secondary pneumococcal infections, spreading directly from the lungs to neighbouring structures, or being carried by the blood stream. *Pleurisy*, with formation of lymph or serum, is hardly a complication, as it is present in practically every case. *Empyema* (20·8) is not so common, but it should be suspected if fever continues into the third week, with dull percussion note, and disappearance or change of the bronchial breath sounds. Rarely a pneumothorax occurs in the course of pneumonia, from rupture of air vesicles into the pleural cavity. *Pericarditis* (2) is frequently associated with empyema on the left side. *Peripheral neuritis*, *nephritis* (0·5), *peritonitis*, *suppurative meningitis* (1), and *arthritis* (0·5), are among the rarer pneumococcal complications. Rarely a true *pneumococcal pyæmia* has occurred with suppurative arthritis and pustules and abscesses under the skin, yielding a thick greenish pus containing pneumococci in pure culture. *Malignant endocarditis* (0·72) (especially of the aortic valve) has been seen in association with pneumonia, and as a result of its specific organisms. In a small number of cases there is pronounced *jaundice* (1·3); a faint icteric tinge is more common. *Acute dilatation of the stomach* sometimes

occurs in the course of the illness, and *parotitis* may ensue in severe cases. *Chronic pneumonia*, *gangrene* and *abscess of the lung*, and *bronchiectasis* are rare sequelæ.

Diagnosis. In the early stages of rigor and high fever pneumonia may be indistinguishable from other *acute illnesses*, such as typhoid, scarlatina, or small-pox. Frequently the pain or distress in one side of the chest will indicate acute disease there, and the absence of breath sounds, or the fine crepitations, at one spot, followed by dullness, bronchial breathing, and bronchophony, will show the nature of the illness. But the pain may be very misleading; it frequently extends to the abdomen, or is felt chiefly in the abdomen, so that *appendicitis*, *peritonitis*, or *cholecystitis* may be first thought of. A careful watch on the pulmonary bases is required to guard against error. In other cases a short cough, with expectoration of rusty sputum, will occur before the development of the physical signs. These last may, indeed, be delayed for five or six, or even ten, days, and they may require much looking for and be first found in unlikely places, such as over the scapula, or at the top of the axilla. The absence of rashes characteristic of the exanthemata, the rapidity of respiration out of proportion to the pulse, the flushed face and bright eye, the characteristic sputum, and the presence of herpes about the mouth are useful points in making a diagnosis. An examination of the blood may help, as the presence of leucocytosis excludes typhoid fever, malaria, and influenza. The Röntgen rays are also of value, as already described.

When physical signs appear, it has to be determined whether pneumonia or *pleuritic effusion* is present, or a combination of both. The diagnosis of these two conditions from one another is dealt with under Pleurisy. The diagnosis from broncho-pneumonia is considered later (*see* p. 158).

Prognosis. The average mortality of lobar pneumonia is about 18 per cent. It is very low in young children, but increases with age. The disease is more fatal to the intemperate, and to those who have been insufficiently fed. Early or violent delirium, failing pulse, lividity and cyanosis, are all symptoms of bad augury. Type III. pneumococcus, against which there is no serum available, is responsible for the gravest cases and the mortality is up to 40 per cent. The prognosis in Type I. cases is better than in Type II., the mortality being 10-15 per cent. in the former and 20 per cent. in the latter. The mortality of Type IV. is 10 per cent. The mortality is higher in America.

Treatment. The patient of necessity takes to his bed, and generally in the height of the disease requires to be supported in a semi-recumbent position by means of pillows or bed-rest. Physical rest with freedom from anxiety is one of the most important elements in treatment. Unnecessary medical examination should be avoided. He should have abundance of warm fresh air, in a freely ventilated room, no less than in any other infectious disease. A diet suitable for a febrile illness should be given (*see* p. 21). Milk will naturally form an important element in it; but eggs and cereals, in the form of milk puddings, Horlick's malted milk, fish or minced chicken, etc., may be added. It is important to consult the patient's taste in such a matter. Beef tea or mutton broth, though not foods in themselves, may be appreciated.

In early stages the bowels should be opened, and a free action of the skin should be encouraged by the use of acetate or citrate of ammonium, with small doses of Dover's powder. This last will relieve the pleuritic pain, or opium may be more frequently given in small doses (3 to 5 minims of tincture) with the saline. Local applications such as antiphlogistin, an ice bag or a poultice may also relieve pain. In mild cases this may be all that is required, but in the severer cases delirium and increasing prostration will have to be met. For the former chloral, chloralamide, and potassium bromide may be employed; but when there is much dyspnoea chloral must be given with caution, because of its depressing effect upon the heart and respiration. For the same reason, morphia must be sparingly used in the later stages. The subcutaneous injection of hyoscine hydro-

bromide ($\frac{1}{100}$ grain) is often useful and safer. For the increasing cardiac failure digitalis is often given, and small quantities of brandy or other spirit, up to the extent of 3 or 4 ounces daily. Where there is right-sided failure, venesection may be required; but oxygen is the best treatment for all these complications. Where there is much secretion in the tubes, ammonium carbonate (5 to 7 grains every three or four hours) may be given. Recently artificial pneumothorax has been employed, and has been successful, in averting pleuritic pain (27). When the crisis is past, and the temperature has fallen to the normal, the treatment requires simply to be directed to the strengthening of the patient by the administration of quinine and other tonics.

It is now generally agreed that Felton's concentrated anti-pneumococcal serum can save life and even abort the disease. At present it is expensive and the quantity limited, so that it is reasonable to limit its use to patients over seventeen, when the prognosis is bad, the special indications being, sudden onset with severe prostration, weak rapid pulse, poor temperature and a leucocyte response, and positive blood culture. It is essential to type the pneumococcus; but this is a matter of a few minutes, and it is only of value against Types I. and II. A Type I. and a Type I. and II. mixed serum is available. It should only be given within the first five days of the disease and the dose in Type II. cases should be double that in Type I. In the latter 20,000 units are slowly given intravenously, diluted in saline, which has been freshly prepared to avoid thermal reactions. Second and third doses of the same size are given at eight to twelve-hourly intervals, and a fourth or fifth dose may occasionally be required.

Administration of Oxygen. When there is lividity or cyanosis oxygen should be given. For practical purposes two methods are available: (1) *The Nasal Catheter.* The cylinder furnished with a fine-adjustment regulating valve is connected first with a Woolf's bottle containing water and then with a rubber catheter which is pushed right to the back of the nose. The connecting tubing should be wide—not much less than $\frac{1}{2}$ inch in diameter. The rate of supply of oxygen is regulated by keeping the bubbling in the bottle at a constant rate. It can be measured by filling a pint measure with water and holding it inverted in a basin of water. On placing the catheter beneath the measure the water is displaced by oxygen. It should take about twenty seconds to collect a pint in the case of an adult. The rate for children may be slower. Instead of the nose the catheter may be pushed as far back as possible through the mouth. A double tube with its nozzles just inside each nostril is another plan; the Müller valve, as used by Davies and Gilchrist, which stops the flow of oxygen during expiration and prevents waste (49) is not really necessary. The wasteful and ineffective way of delivering oxygen through a funnel should never be used.

(2) *The Oxygen Tent.* The principle of the tent is that the patient lies in an atmosphere enriched with oxygen (40 to 60 per cent.), while the carbon dioxide, moisture and heat are removed. A number of different tents have been described. In the tent in Plate 4, A, the heat and moisture are removed by ice-containers, which are let in through the roof of the tent, while the CO_2 is removed by ventilating the atmosphere through a canister of soda lime by means of an "injector" screwed into the head of the cylinder, so that this pressure of oxygen in the cylinder provides the motive power (49). Clinical apparatus is provided for determining the percentage of O_2 and CO_2 in the tent. There is experimental evidence from arterial puncture on pneumonia patients, that the tent is more effective than the nasal catheter; lives have been saved with the tent, which would almost certainly have been lost if treatment with the catheter had been persisted in. The writer has saved 20 out of 28 grave cases of pneumonia by means of the tent. The question arises whether CO_2 should be given in addition to oxygen. This can be effected by preventing complete absorption of CO_2 in the circuit, so that the patient partly rebreathes the CO_2 he has himself produced. In the writer's opinion CO_2 may perhaps be given in the early stages of pneumonia, to increase the

depth of breathing and promote a slight cough and to loosen the viscid plug of mucus, which is the primary cause of the condition, as already described. By this means the disease might be aborted. But in the later stages, when the heart is fatigued, oxygen alone should be used. It is a remarkable fact that pleuritic pain often disappears in the tent.

FRIEDLÄNDER PNEUMONIA

From observations on cases in which lobar pneumonia has been due to the *Bacillus pneumoniæ* of Friedländer, it appears that it is generally a severe disease with a bad prognosis, that the lung in a fatal case oftener presents a blackish-grey than a red colour, and that the section is covered with a slimy mucus. The alveoli contain numerous bacilli and desquamating epithelium. Suppuration and gangrene are much more frequent than in the usual form, and the temperature is more variable. The bacillus of Friedländer may be accompanied by the pneumococcus, and it may be the cause of a lobular as well as a lobar pneumonia.

BRONCHO-PNEUMONIA

(*Catarrhal, Lobular or Interstitial Pneumonia*)

Ætiology. (1) *Primary Broncho-pneumonia.* When the pneumococcus in pure culture attacks the lungs in children under five years old, it may produce a typical lobar pneumonia, but it more often attacks the alveoli in patches over the lung. Such cases have been called *primary broncho-pneumonia* (West) or *primary lobular pneumonia*. Except for the patchy distribution in the lungs, these cases resemble the lobar pneumonia just described, and there is no associated bronchitis. There is no necessity to say anything more about them. (2) *Broncho-pneumonia* proper, sometimes called *secondary broncho-pneumonia* or *acute interstitial pneumonia*, always starts from inflammation in the smaller bronchi, which spreads into the surrounding air vesicles. It occurs commonly in children under three years of age. It is a frequent complication of measles and whooping cough, and also follows other infectious diseases (scarlet fever and influenza, etc.). Ill-nourished town-dwelling children are thought to be more liable to broncho-pneumonia, and it is probable that rickets also disposes to it. Broncho-pneumonia occurs in adults from inhalation of foreign particles, especially septic materials from the throat, into the lungs (*inhalation pneumonia*); it is a common result of the spread of diphtheria down the bronchial tubes to the bronchioles; it is often a terminal event in any long-continued wasting disease, especially in elderly people who have been obliged to lie recumbent for weeks; when it attacks the most dependent parts of the lung it is known as *hypostatic pneumonia*. It may occur after operations under general anæsthesia, and it is a frequent cause of death in those who have been nearly drowned. Carcinoma of the œsophagus may be fatal by invading the lung and setting up pneumonia. But septic particles may reach the lung by the blood vessels, and pyæmia is characterised by its suppurative pneumonic foci. To many of these cases the term *septic pneumonia* is applied.

The bacteriology of broncho-pneumonia is complicated, and a great number of bacteria have been found in various combinations. A specific fever, such as measles or influenza, is to be regarded as exerting a depressing effect on the resistance of the individual, so that the lungs are invaded secondarily by various organisms. In the United States army the hæmolytic streptococcus was found to be the most important agent and the most fatal; but the pneumococcus, *B. influenza* and *Staphylococcus aureus* were also present on occasions. Friedländer's bacillus and in cases of diphtheria the Klebs-Löffler bacillus also occur.

Morbid Anatomy. In broncho-pneumonia the consolidation is scattered throughout the lung in the form of nodules, often separate, but tending to

coalesce, so as to form larger masses (*confluent broncho-pneumonia*), but even then still to be distinguished by the eye from each other. On section the solid lung is seen to consist of a number of small grey foci surrounded by dark red zones of hæmorrhage, œdema and collapse. The lung is soft and friable, and on squeezing a bead of pus exudes from the small tubes. The process is sometimes called *splenisation* of the lung. Microscopically the characteristic lesions are interstitial inflammation affecting the bronchial and alveolar walls, and peribronchial lymphangitis, the infiltrating cells being polymorphs in the severer cases. The lumen of bronchus and alveolus becomes filled with catarrhal contents, *i.e.* chiefly large endothelial cells; while in cases of some duration there is a formation of new fibrous tissue in the bronchiolar and adjacent alveolar walls. Hence the name *interstitial broncho-pneumonia* which is often applied to the condition. The streptococci swarm in the bronchioles and thrombosed lymphatics. When the inflammation reaches the surface there is usually some pleurisy. In very acute and fatal cases there is no fibrous tissue formation, and the streptococci are seen invading the alveoli; abscesses may be formed in the lung.

Symptoms and Physical Signs. The former are cough, dyspnœa, and pyrexia; the latter vary with the extent and position of the separate lesions. If the child has already a cough, with rhonchi and râles over the chest, from a preceding bronchitis, the implication of the alveoli may be indicated by a rise of temperature to 102° or 103°, by the cough becoming short, dry, and painful, and by the râles becoming more abundant and taking on a consonating character. But in many cases there are no rhonchi, and the physical signs consist of one or more areas, more or less extensive, in one or both lungs, in which rather sharp crackling râles are heard, with little, if any, change in the percussion note, or areas, also irregular in distribution, over which there is dulness, with bronchial breathing and bronchophony due to the aggregation of a sufficient number of consolidated lobules. Such areas may enlarge or diminish, and spread or clear up as the disease progresses. The sputum consists of mucus or muco-pus with or without streaks of blood, but young children usually swallow it. Exceptionally there may be free hæmoptysis.

The course of the disease is not so definite as in pneumococcal pneumonia. It may end in a week, but often goes on for three or four weeks, or even more. The temperature is generally remittent or even intermittent, and usually falls by lysis; it may be very irregular. The breathing is rapid, and is *inverted*, which is often valuable in diagnosis. There is a quick inspiration, the breath is held for half a second, expiration then occurs with a grunt, and inspiration again follows without an interval. The lower intercostal spaces are depressed during inspiration. There is much cough; the face is flushed, or in severer cases pale and livid. The pulse is quick and small. Delirium is often present. The physical signs frequently alter in the course of the illness, indicating the clearing up of disease at one part, and fresh outbreaks in others; the disease often attacks both lungs. Recovery is mostly gradual, and not sudden, as in pneumococcal pneumonia. Convulsions may precede death.

Diagnosis. Broncho-pneumonia may be confounded in its early stages with other *acute illnesses* characterised by high fever, such as typhoid fever; and the liability of children to marked cerebral symptoms from any acute illness may lead to a diagnosis of *meningitis*. The preceding bronchitis and the predominance of the chest symptoms may prevent a mistake, but an opinion may have to be suspended for a few days. Long-continued broncho-pneumonia may give rise to a suspicion of *tuberculosis*, in which high fever, universally scattered râles, lividity, and cough are prominent symptoms. In *capillary bronchitis* there are dyspnœa, lividity, and râles, but the râles are often confined to the bases; there is no bronchial breathing. There may be profuse purulent expectoration. The diagnosis of confluent broncho-pneumonia from lobar pneumonia may be difficult. In the latter case the signs over the lungs are more uniform, and there

may be a crisis. In broncho-pneumonia there is bronchiolitis, as indicated by consonating râles of varying coarseness in both lungs, and since the patches do not resemble one another in the state of development of the inflammatory process, the breath sounds will change between puerile and fully developed bronchial breathing of varying pitch. But the main distinction is that in broncho-pneumonia the fever is longer and resolution slower. A typical radiogram is shown in Plate 4, B, p. 156.

Prognosis. Though this form of pneumonia is much more fatal than the pneumococcal variety, the prognosis in any given case must depend upon the general progress of the symptoms. Cases that are apparently desperate often recover, and an unfavourable opinion should be given with some caution. In the broncho-pneumonia of old people, and in that which is due to the inhalation of solid particles, the prognosis is more grave.

Treatment. The treatment may be conducted on the same general principles as in the case of ordinary pneumonia. The room should be well ventilated, with free access of air to the patient; open-air treatment has been tried with success. Oxygen should be given continuously for long periods if there is respiratory distress or lividity; the oxygen tent is especially suitable. Tr. belladonnæ in doses of 3 to 5 minims may be given to quite young children in order to dry up the pulmonary secretion. Injections of atropine are also sometimes given. Expectorants are not generally approved of for young children, as they have no power of coughing up sputum. Severe cases often require stimulants to be administered rather freely—*e.g.* for a child three or four years old 20 minims of brandy every hour; or 1 or 2 minims of liquor strychninæ may be injected two or three times daily at this age, and smaller quantities in infants.

ABSCESS OF THE LUNG

Abscess may be a result of pyæmia, and of acute pneumonia. It may result from the same agents that cause gangrene of the lung, *q.v.*, or from the spread of neighbouring suppuration, such as empyema, or subdiaphragmatic abscess, or hydatid disease, or actinomycosis. The differential diagnosis of abscess from consolidation of the lung is difficult until the abscess has burst and discharged pus. Then the cardinal signs are (1) purulent sputum, which may be foul; (2) cough and explosive expectoration; (3) elastic tissue with alveolar arrangement in the sputum; (4) circumscribed dulness on percussion; (5) X-ray appearance of a cavity with a fluid level. When the fluid contents of the cavity have been coughed up there may be the usual signs of a cavity, such as tympanic resonance if the cavity is large, cavernous or amphoric breathing, metallic tinkling, and pectoriloquy. The multiple small abscesses of pyæmia are not recognisable as cavities; indeed, their presence is usually masked by the surrounding consolidation, or pleuritic effusion. (Plate 5.)

Prognosis and Treatment. *Bronchoscopy* has revolutionised the outlook; after localising the abscess by observing from which bronchus the pus is coming, the principle is to remove the obstruction, which may be complete, partial, or of a valvular nature; pus is sucked out of the abscess cavity and gomenol oil may be instilled into it. After removing the main mass of pus, cultivation of the bottommost layer may yield the infective agent in pure culture, so that a vaccine can be prepared. Vincent's spirillum and fusiform bacillus are not uncommon. The size and shape of the cavity may be determined by instilling lipiodol through the bronchoscope. A single bronchoscopy may result in healing; otherwise it may be repeated. Other factors leading to suppuration have been found by bronchoscopy to be weakening of the cough reflex, overdosing with morphia and atropine, rarely the presence of a foreign body, or non-malignant neoplasm, such as a polyp and rare infections like blastomycosis and actinomycosis (64).

FIBROID LUNG

(Fibrosis of the Lung, Chronic Pneumonia)

Ætiology. This form of lung disease is comparatively rare except in children, the great majority of chronic inflammations of the lung tissue in adults being associated with tubercle. The cases in which a chronic inflammation is independent of tubercle, and to which the name fibroid lung is given, arise only rarely from a preceding acute lobar pneumonia; but broncho-pneumonia is a more frequent antecedent. Chronic bronchitis and pleurisy are also causes in other instances.

An important class of fibroid lung is that occurring among workers in various factories and mines, known as *pneumokoniosis*. Here the repeated inhalation of an atmosphere laden with the dust of coal, metal, *e.g.* emery, quartz, cotton fibre, fluff, etc., provides a lifelong source of irritation. The disease has received different names according to the particular irritant concerned—*anthracosis* (coal dust), *silicosis* (silica, described later), *asbestosis* (asbestos).

Morbid Anatomy. The characteristic feature of the lung is fibrosis. When fibroid lung results from pneumonia or bronchitis the strands of fibrous tissue, which traverse the lung, originate from the inflammation in the walls of smaller bronchi and from peri-bronchial lymphangitis (as described in broncho-pneumonia), because the lumen of the tubes becomes entirely obliterated with granulation tissue. This *obliterative bronchiolitis* is thus essentially the same process as that which produces bronchiectasis, except that in the latter case the larger tubes have been affected and cavities formed. Hence bronchiectasis and fibroid lung are commonly associated, but fibroid lung appears alone, if the inflammatory process is confined to the smaller tubes (10). With the growth of the fibrous tissue contraction takes place, and the lung may be reduced to two-thirds or half its natural size. The contraction of the lung leads to displacement of organs, and, as usually only one side is affected, the mediastinum is pulled in that direction. In late stages the whole lung may be converted into a dense mass of fibrous tissue, of various shades of grey from the presence of pigment, tough in consistence, and creaking under the knife. In pleurogenous cases the mode of production is probably different, and in these cases the lung is fixed to the chest by a thick fibrous layer.

Symptoms and Course. The disease is generally chronic, and patients in whom it is recognised have usually complained for some months or years. The patients are short of breath, and have cough and expectoration, which vary with the extent of the cavities in the lungs (*see* Bronchiectasis). The patient is often thin, but may be well nourished, and is at any rate for a time free from the fever, night sweating, and general constitutional disturbance observed in phthisis. Hæmoptysis is often present. The disease is commonly unilateral; the corresponding side of the chest is retracted, the shoulder depressed, and the angle of the scapula tilted outwards; the impulse of the heart is shifted towards the affected side, and the healthy side of the chest is hyper-resonant. The affected side expands but little; it is dull on percussion. There is deficient air entry when the small tubes are obliterated, otherwise there is bronchial breathing, bronchophony, pectoriloquy and consonating râles. Tactile vocal fremitus is variable. The lung affected shows some opacity to X-rays, while the ribs show "roof tiling" (*see* p. 168). Thickening or *clubbing* of the finger ends (*see* p. 565) is often pronounced. Eventually there may be right-sided heart failure.

Diagnosis. The condition has to be distinguished from phthisis, from chronic pleurisy with effusion, and from malignant growth in the chest. From *phthisis* the absence of fever and constitutional disturbance is the chief distinguishing feature; the disease is often rigidly unilateral and basal, whereas

phthisis, which is usually apical, rarely reaches an advanced stage in one lung without affecting the other; and tubercle bacilli are not found in the sputum. *Pleuritic effusion* of old standing with retracted chest may closely resemble the fibroid lung, and exploration with a needle may be required to clear up the diagnosis. The history with *intrathoracic carcinoma* is likely to be short. There may be pains and extensive consolidation, and signs of pressure or displacement of the heart. X-ray should always be carried out, and bronchoscopy.

Prognosis is ultimately bad, but the course may be very slow, extending over ten or fifteen years. Children sometimes recover. Death may take place from failure of the right heart, or from the gradually increasing exhaustion which follows profuse discharge, or from metastatic abscesses, in particular cerebral abscess.

Treatment. The patient should be placed under the best possible climatic and hygienic conditions. He should have bracing air in the summer, but a warm climate in the winter; avoid exposure to chills at all times; and have nourishing diet and tonics, such as quinine, iron, and cod-liver oil. Cough, expectoration, and other symptoms should be treated as they arise in the same manner as directed under Phthisis and Bronchitis and Bronchiectasis.

Anthracosis. The coal miner's is a healthy life, which is surprising considering the amount of carbon that is deposited in the lungs, making them black to the naked eye. Carbon seems to protect against tuberculosis. In spite of this, in certain areas, such as S. Wales, silicosis occurs and causes death from chronic pulmonary disease, while the percentage of silica in the lungs is much above normal in miners who have died from other causes (51).

Silicosis. This is a widespread industrial disease, for which the workman can claim compensation, and which has been intensively studied in S. Africa, owing to its prevalence in the Rand gold mines (52). In the *simple type* the silica causes nodular fibrosis of the lungs and root glands; this forms a characteristic uniform discrete mottling on the X-ray film in the upper half of one or both lung fields, and later becomes generalised; the opacities are usually intenser and better defined than in generalised tubercle, though the resemblance may be close. An early suspicious appearance is a generalised arborisation, like a leafless tree, due to increased density of the bronchial or possibly the vascular tree in the lungs. At first there are no symptoms, but later there is a cough, with recurrent "colds," shortness of breath, moderate expectoration, but no emaciation; there may be pleurisy. In the *infective type* tuberculosis is added, because after inhalation the silica becomes converted by hydration into colloidal silicic acid. Mineral silicates also become decomposed by the CO_2 of the tissues into silicic acid. The latter causes a granulomatous mass to be formed, consisting of a central area of necrosis, surrounded by inflammatory layers. Tubercle bacilli, present in such small numbers that the tissues would ordinarily deal with them, multiply rapidly in the central area, become too many for the local defences and so spread to other parts (50). The opaque areas in the X-ray film become more irregular in size and distribution, and hilar shadows become prominent, and the case becomes one of fully developed open pulmonary tuberculosis. Prevention consists in blasting at the end of the day's work to avoid dust, water to lay the dust and good ventilation.

Asbestosis. Asbestos is iron and aluminium silicate. The disease is very insidious, developing after six to twelve years' work. The lower lobes are especially affected, showing a diffuse fibrosis with increased thickening of the pleura. The diaphragm becomes thick and of cartilaginous hardness and invades the base of the lung, giving a very characteristic irregular or woolly appearance of its upper surface in X-ray films. Eventually bronchiectasis supervenes; there is some doubt as to whether there is any particular liability to tuberculosis. The sputum contains characteristic "asbestosis bodies"; otherwise the symptoms resemble those of fibroid lung.

GANGRENE OF THE LUNG

This is a comparatively rare disorder, which may arise, however, in a variety of circumstances. It is one of the terminations of acute lobar pneumonia, especially in cases dependent on Friedländer's bacillus, and it occurs rarely in phthisis; it may result from the invasion of the lung by adjacent diseases like carcinoma of the œsophagus, abscesses, and suppurating hydatid cysts, from the pressure of aneurysm on the root of the lung, and from injuries to the chest setting up pneumonia or empyema; as a result of foreign bodies lodged in the bronchus, and from the presence of secretions retained in dilated tubes; from the passage into the lung of particles from septic diseases in the mouth, throat, larynx, œsophagus, such as carcinoma of the tongue or larynx, sloughing of the tonsils, diphtheria, carcinoma of the œsophagus; from particles of food drawn into the lung by accident, or during vomiting, especially in persons who are drunk, insane, comatose, or suffering from laryngeal paralysis; or from infected water inhaled during immersion. Gangrene of the lung sometimes arises in pyæmia after otitis, bedsores, puerperal disorders, etc. It is determined by the presence of putrefactive organisms, including the *Bacillus Welchii*.

Morbid Anatomy. The affected portion of lung is of a dirty, greenish-brown, or black colour, soft, readily breaking down or even diffuent, and often emitting an offensive odour. It is generally surrounded by consolidated pneumonic tissue, into which it may gradually pass, or from which it may be more or less sharply separated off by a line of demarcation; thus in some cases the lesion is diffuse, in others definitely circumscribed. The gangrenous tissue may break down, and be expectorated, so as to leave a cavity with ragged, shreddy walls; and occasionally such a cavity opens into the pleural sac and causes pyo-pneumothorax.

Symptoms. Gangrene of the lung occurring, as it often does, as a secondary lesion just before death, may be overlooked. On the other hand, its symptoms may stand alone, or overshadow those of the primary lesion. Fœtid expectoration and fœtid odour of the breath are the most prominent. The latter may be very penetrating; it is carried to a great distance, and makes it almost impossible for other persons to live in the same room with the patient. The sputum is dirty grey or greenish-brown, or black, from altered blood; and either fragments of gangrenous lung tissue are found, or the microscope detects the typical elastic fibres (*see* p. 170). Occasionally hæmoptysis takes place. Cough, pain in the side, and irregular, and mostly intermittent, pyrexia are also present. The physical signs are those of consolidation and cavity proportionate to the extent of lung disease—viz. dulness, bronchial or cavernous breathing, bronchophony, and medium or coarse râles; but their value in diagnosis must depend a good deal on the preceding disease, if any. The illness may begin with rigor and pain in the side, or with hæmoptysis, or with recurring attacks of fever and fœtid expectoration; in most cases these are soon followed by prostration, with quick small pulse, dry tongue, and death at no great distance of time. Some cases, however, last for months or years, with much variation in the intensity of the symptoms, but without escaping a fatal termination. And in a few cases, with probably a very small patch of gangrene, recovery actually takes place.

Treatment. This is similar to that of fœtid bronchitis or bronchiectasis. Successes have been obtained with arsenobenzol and novarsenobenzol. A gangrenous cavity is sometimes amenable to the surgical treatment of antiseptic incision and drainage or bronchoscopy might be used; and the operation should be considered when a certain diagnosis can be made, and the associated conditions are in themselves not necessarily fatal.

PULMONARY TUBERCULOSIS

Tuberculosis of the lung occurs in several forms. In one there is a general distribution of minute tubercles throughout the organ, arising acutely, and determined by the carriage of the tubercle bacilli by the blood from some other part, such as a bronchial or cervical gland, or a joint or kidney, or less commonly from a focus of chronic disease in the lung itself. This acute form is often part of a general miliary tuberculosis, in which tuberculous meningitis is usually the most striking feature (see p. 88). The other forms of pulmonary tuberculosis have this in common, that the affection of the lung usually makes the chief part of the clinical picture.

Phthisis (φθίω, I waste) or *consumption* is a chronic disease of adults or later childhood in which tubercles are formed and multiply in one small part of the lung, usually the apex, and spread with very varying degrees of rapidity to other parts of the lung. It is thus at first entirely local. The later changes are assisted by the action of other organisms, especially the *Pneumococcus*, *Streptococcus*, and *Staphylococcus pyogenes*. Apical phthisis probably starts as a direct infection of the lung due to inhaled tubercle bacilli. Much discussion has taken place as to why the apex is primarily affected. Keith has pointed out that this part of the lung is less ventilated than other parts, because the top of the thorax is relatively immobile, the greatest movement taking place at the diaphragm and over the lower part of the chest wall. Since the ventilation is least at the apex, it may well be that the circulation is also least, so that the bacilli find a favourable nidus. Another explanation, not a very probable one, is that the infection begins in the tonsils and spreads along the cervical lymphatics direct to the apex of the lung across the pleura.

Hilum phthisis, or *peribronchial phthisis*, is also a chronic disease of the lungs, which occurs rather uncommonly in adults; but it is the usual form that chronic pulmonary tuberculosis takes in young children. Tuberculous infiltration of the bronchial glands and of the lymphatics draining into them from the surrounding lung is the chief lesion. It has already been explained that the lung provides the primary focus in these cases (see p. 85). Tubercle bacilli are taken up by the lymphatics of the lungs, which become gradually choked or obliterated in the process, beginning at the hilum and gradually extending outwards towards the surface of the lungs. Hilum phthisis may give rise to a more acute tuberculous process at any place in the lungs. Usually, however, it heals in course of years, and it has been suggested that the pulmonary scars found so frequently at post-mortem are the results of this disease of childhood, now extinct. In this case the apical phthisis of adults is a reinfection in later life, although whether the patient who has once had hilum phthisis is specially sensitive to a fresh infection or specially resistant is open to doubt.

Epituberculosis is a widespread consolidation of the lung in children round a small tuberculous focus; the consolidation is not itself composed of tuberculous granulation tissue, but may be either a non-specific infiltration resembling on a large scale the swelling that occurs in a positive Mantoux test—it has appeared immediately after an injection of tuberculin—or a widespread collapse from pressure on a bronchus by a tuberculous gland, as it has quietly cleared up after removal of the obstruction (57). There may be dulness and bronchial breathing and the X-ray may show a uniform shadow, usually in the middle of the right lung, spreading out from the hilum with its apex towards the periphery. Puncture of the area has disclosed tubercle bacilli. It is distinguished from pneumonia, as in the latter the apex of the shadow is towards the hilum, and it resolves in a few days. In epituberculosis resolution takes place after some weeks; the prognosis is good.

Tuberculous broncho-pneumonia is an acute tuberculous process occurring chiefly in children or young adults, in which caseous tuberculous foci, with com-

mening cavity formation, are scattered through the lungs. In children it commonly results from the ulceration of a caseous gland into a large bronchus, with rapid dissemination by inhalation of the highly infective material throughout the lung. The apex usually is not specially affected. *Acute pneumonic phthisis*, which has been called "galloping consumption" or *Phthisis florida*, is a still more acute process, and is described later.

The ætiology of pulmonary tuberculosis has already been discussed in the section on tuberculosis in general (see p. 83).

Morbid Anatomy of Phthisis. Tubercles form and develop in the lungs in the most typical way, with their giant cell systems, and their tendency to caseate and break down (see p. 86). In the common apical lesion the process starts in the wall of a small terminal bronchus. Caseation occurs, and the tuberculous mass breaks down; the material is discharged through the bronchus, and a minute cavity is formed connected with it. Meanwhile the process spreads into the neighbouring lung tissues, which become consolidated partly by caseation and partly by cellular inflammatory exudate. The solid areas are dark in colour, with small white caseous tubercles in bunches scattered through them, and usually a fair amount of consolidation takes place before much cavity formation is seen. Cavities or vomicæ are formed by a mixed process of caseation and suppuration. Adjacent cavities run into one another, and ultimately the lung may be extensively hollowed out. In their earlier stages the walls are often formed of caseous deposit, but in old vomicæ they are quite smooth. They are often traversed by bands, or trabeculæ, which contain pulmonary vessels. The vessels resist the destructive process, whereas the bronchi are generally ulcerated in proportion as the cavities enlarge, and into each cavity one or more bronchi open. The contents of vomicæ are caseous matter, *débris* of lung tissue, and pus. The latter predominates in the older cavities; the quantity is very variable, and it may be so small, under certain circumstances, that no expectoration takes place for considerable periods. It is only rarely that decided putrefaction takes place in phthisical cavities.

The first deposit of tubercle takes place one or two inches below the apex of the upper lobe in the subclavicular region; and fresh deposits occur lower and lower down. This invasion of fresh parts of the lung takes place by direct contiguity, by lymphatic channels, and largely through the bronchi; infective particles are inhaled into them, and thus start fresh centres of disease. By the time that tubercle forms at the lower levels the first lesion may have led to considerable consolidation; and later on, when tubercle is being deposited towards the base, the middle part of the lung will have solidified, and the apex may contain a large cavity. Again, the progress of the disease, while unequal in any one lung, is unequal in the organs on the two sides; and so, in an advanced case, it is common to find the most extensive disease at one apex, and the most healthy tissue, or the only healthy tissue, at the opposite base. A primary lesion of the lower lobe (primary basal phthisis) is rare.

In cases where the resistance is low, many separate foci may originate more or less simultaneously throughout the lungs by inhalation through the bronchi of sputum from some primary focus of infection in the lung. Infiltration of the lung surrounding each of these secondary foci may take place before the caseous matter can be discharged. The whole lung becomes completely solid, being filled with partly caseous and partly gelatinous-looking material, the latter representing parts of the lung not quite so completely destroyed (*caseous lobar pneumonia*, *acute pneumonic phthisis*). In other cases at post-mortem large cavities are in process of formation, their walls being extremely ragged. If the patient dies in a less advanced stage, the lungs will show numerous discrete caseous and gelatinous areas with early cavity formation (*caseous broncho-pneumonia*), since here the areas have not had time to coalesce to produce the diffuse pneumonic condition.

But in the majority of cases this process of destruction does not have full play. The inflammatory changes present varying changes of activity in different cases; and the mischief may be stopped for long periods one or more times in its course, or may even become abortive at an early date, and go no farther. The development of *fibrous* tissue is the important agent here. It is rarely absent in any but the most acute cases, and in the chronic cases it forms a large proportion of the remaining tissue of the diseased lung. In the consolidated lung there are numerous bands running in the course of the interlobular septa, surrounding the bronchi, the blood vessels, and the cavities, and forming a dense layer under the visceral pleura (fibroid phthisis). The fibrous tissue is frequently deeply pigmented, and is mixed here and there with caseous masses. By its contraction it tends to diminish the size of the cavities, and opposes some resistance to destructive processes; and in some favourable cases a small deposit of tubercle may be ultimately converted entirely into a mass of pigmented fibrous tissue, which, indeed, replaces a similar amount of healthy lung, but is otherwise harmless. In these cicatrices it is not uncommon to find calcareous particles, from the deposit of calcium salts in the caseous material; and around such a cicatrix may arise the condition known as *compensatory emphysema* (see p. 146). However, it must not be supposed that fibrous tissue formations and calcification is always the final stage in the healing process. Serial X-ray examination has shown that deposits of this nature may eventually be absorbed and disappear altogether when the patient regains perfect health.

Pleurisy may be present at quite an early stage; it may be dry; but a clear, straw-coloured sero-fibrinous effusion is very common, occurring late in the disease or heralding its approach. Such an effusion may be bloodstained; its characters are described later, and it may be gradually absorbed as the process heals or a dry pleurisy is left and the final result may be the formation of a thick layer of fibrous tissue over the affected portion of lung, commonly uniting the organ firmly to the wall of the chest. This adhesion of the lung has an important influence, for, if the process of excavation advances to the surface at a point which is not adherent, the vomica may ulcerate through, and discharge its contents into the pleural cavity, leading, on the one hand, to an acute pleurisy, generally of the purulent variety—*empyema*; and, on the other, to the entrance of air into the pleural sac—*pneumothorax*, and if fluid is present a hydro- or pyo-pneumothorax.

Another important result of the destruction of tissue is *hæmorrhage*: in earlier stages this follows from congestion alone; in later stages the vessel walls are directly invaded by tubercle, and hence may be eroded, or they may be weakened and dilate so as to form aneurysms, which may reach the size of a pea or bean, and ultimately give way at the thinnest part.

During the course of phthisis tubercle may attack other parts of the body. Laryngeal tubercle results from the continued passage of tubercle-laden sputum through the glottis. Tuberculous ulceration of the ileum or cæcum and fistula in ano result from the swallowing of sputum and its gradual passage through the alimentary canal. Tuberculosis of the peritoneum, kidney, epididymis, vesiculæ seminales, uterus, and its appendages, ribs, spine (with resulting abscesses such as psoas abscess), and other bones and joints, may co-exist with pulmonary disease, either resulting from it or in some cases acting as the primary focus. General tuberculosis with meningitis sometimes closes the scene. Addison's disease is rare. Lardaceous disease of the liver, spleen, kidneys and intestines was found in 20 per cent. of fatal hospital cases some years ago. The heart is small. In acute cases, owing to anæmia or lack of pulmonary aeration, the muscle shows fatty degeneration. In chronic fibroid disease the right ventricle is hypertrophical. Fatty liver is common.

Clinical History of Phthisis. Phthisis may run a rapid or a slow course.

The description which follows will mainly apply to a case which lasts from six months to a few years.

The onset is variable. Many cases begin with cough and expectoration of muco-pus or pus for which no cause can be given, or which is referred to some chill or exposure. Other cases begin with hæmoptysis or spitting of blood. The patient may have been apparently in good health, when sometimes after an effort, but quite as often when still, or walking or doing something which involves no strain, a tickling is felt in the throat, the patient coughs, and is surprised and alarmed to find that what he spits is blood. Thereupon he may expectorate a few drachms or an ounce, or even half a pint. This may remain the only symptom, and an examination of the chest may reveal nothing. But after a time, with or without a fresh loss of blood, cough and expectoration supervene, and the case develops like others. In a small number of cases the first apparent departure from health is an acute pneumonic process in one upper lobe, which only partially clears up, while cough and expectoration persist, and the case takes on all the features of phthisis; and in others the first recognisable illness is a pleurisy with serous effusion occasionally bloodstained, which may even appear to recover completely, and yet be followed by the usual pulmonary changes.

The disease is also very variable in its course in different cases. Patients with the earliest symptoms, whether hæmoptysis, or cough, or wasting, placed under favourable conditions of climate and hygiene, may completely regain their health; and it has long been known that in persons killed by accident, or dying of disease unconnected with the lung, cicatricial and pigmented patches, with perhaps calcareous deposits, are found in the apices which can only be regarded as the remains of former tubercles.

If, however, the infection is well established before being submitted to treatment, the result cannot be so satisfactory. Thus the disease may be fatal in three or four months, or it may last twelve or fifteen years before finally killing the patient; and in this time its progress will be very unequal, often quiescent for months or a year or two, and then making great strides, with hæmoptysis or much fever. While the more rapid cases are fatal chiefly by the extent of lung involved, the cases of longer duration threaten life by a number of complications, some of which are lesions of the lung itself, such as hæmoptysis, empyema, and bronchitis; while others involve distant organs, such as tuberculous meningitis, ulceration of the intestines and diarrhœa, nephritis, and lardaceous disease of the viscera.

Local Symptoms. These will now be described somewhat more in detail.

Cough. This is a very common symptom and generally, though not always, present as long as the disease is in any degree active. The cough is easy or dry, depending on the amount of sputum and ease with which it can be expectorated; with extensive cavities, when the sputum sinks to dependent parts of the affected lobe, it occurs in prolonged attacks, painful to the patient, distressing to those about him, and lasting perhaps more than a minute. With laryngeal complication the cough acquires a hoarse or husky quality.

Dyspnœa. Shortness of breath is often early noticed when there is bronchial spasm; the latter may sometimes be due to allergic asthma. Dyspnœa becomes very marked as more and more of the lung is diseased, and so the surface available for interchange of blood gases is diminished.

Expectoration. In the early stages this is not different from the sputum of bronchitis—that is, it is either simply mucous or muco-purulent; and this is accounted for by the bronchitic processes which frequently accompany phthisis. But sometimes comparatively early, and always in later stages, the sputum becomes purulent, of green or greenish-yellow colour, opaque, and quite free from air bubbles. If it is very fluid, the individual sputa may run together and lose their separate form; but the sputa of phthisis often keep separate long after expectoration, and, from the round, flat shape that they assume in the sputum vessel, they are called *nummular*, or coin-shaped. This is no doubt due to the

accumulation of the secretion in cavities in the lungs, and hence it constantly occurs in phthisis, but may also be present in cases where the cavities are produced by dilated bronchi (bronchiectasis). The microscopical examination for tubercle bacilli is described later.

Hæmoptysis. When hæmoptysis occurs as the first sign of phthisis, the blood is generally bright red and frothy; it is expectorated in variable quantities, and, as a rule, for some hours or days the patient continues to spit pellets of blood which have a darker and darker colour, become gradually less frequent, and then cease entirely. There may at this time be no other sputum. In later stages, when the disease is well established, the muco-purulent or purulent sputum is often streaked or stained with blood. A few streaks in the sputum may proceed from small vessels in the bronchial mucous membrane, but more characteristic of phthisis is the intimate mixture of bright blood with the sputum, or the discharge of pellets of coagulated blood frequently during the day. From time to time may occur more abundant hæmorrhages, like those first described, in which the blood comes up apart from the ordinary secretion; and if a large vessel is ulcerated, or, what is more often the case, if a small aneurysm in a cavity ruptures, several ounces or a pint or two of blood may be discharged within a short time, and death may follow rapidly. Hæmoptysis tends to occur rather more frequently at night than in the daytime, possibly owing to the cold (28).

Physical Signs. From the clinical point of view three stages of apical phthisis are described (Turban-Gerhardt classification). In Stage I., which represents early cases, the disease is limited to a small area of one or both apices. In Stage II. there is consolidation, the disease affecting the whole or the greater part of one lobe. Stage III. represents still more extensive disease and all cases where there is considerable cavity formation.

The physical signs are best described according to these stages. In the *first* stage they may be very slight, and vary considerably in different cases. The eye or the hand may detect a slight impairment of mobility on the affected side. For this purpose the relative movements should be watched during tranquil and during full respiration. Careful percussion of the apex may give slight impairment of note as compared with the opposite side. There is normally a band of apical resonance, 4.5 to 5 cm. ($1\frac{3}{4}$ to 2 inches) wide, running over the shoulder (*Kronig's isthmus*). This may be narrowed in disease. An impaired note may also be obtained just below the clavicle, on the clavicle, or in the supra-clavicular fossa. The patient should be sitting in a relaxed position. Auscultation often gives a diminution of the vesicular murmur and the presence of fine or medium râles heard best towards the end of the first inspiration after coughing. The expiratory murmur may be loud and prolonged, as in bronchial breathing, and this may be associated with an increase of vocal resonance. It is, however, very important to remember that prolonged loud expiratory murmur with loud vocal resonance is not uncommon upon the right side in healthy individuals, and especially in females. And, as a rule, repeated examinations at short intervals are needed before one can with confidence state that there is evidence of apical phthisis from the physical signs in an early case. Impairment of note and râles are the most trustworthy signs. However, sounds resembling very closely crackling râles are sometimes produced in the sterno-clavicular joint. Irregular, jerky or wavy breathing—the so-called cog-wheel respiration—is of no diagnostic significance.

In the *second* stage (consolidation) the physical signs are in many respects similar to those of the second stage of pneumonia. According to the extent of lung involved, there is more or less impairment of mobility of the affected side; and when the progress has not been unusually rapid, there is obvious depression of the supra-clavicular and infra-clavicular regions, caused by contraction of fibrous tissue, or perhaps by the earliest destruction of tissue, producing cavities as yet too small to be recognised by physical signs. On percussion there is

increasing loss of resonance as the case goes on ; but the dulness is rarely so absolute as that which occurs over a pleural effusion. On auscultation bronchial breathing of different qualities and pitch is heard, and the voice and cough are loudly bronchophonic. Consonating râles and short rhonci are commonly heard.

It is in the *third* stage (excavation), when the disease has existed some time, has seriously involved one lung, or has already begun to attack the other, that the modifications in the shape of the chest are most obvious. On the most affected side the chest takes on the type of extreme expiration. It is flat, long, and narrow ; the shoulder is depressed and sloping ; the lower angle of the scapula is displaced inwards ; while the upper ribs in front are wide apart, the lower ribs are crowded together, and the epigastric angle is reduced to its smallest size. The crowding together of the ribs gives an X-ray appearance, called "roof-tiling," generalised mottling is shown in Plate 6, A, (see p. 170). In addition to this general change in the chest, there is retraction of the upper part of the chest and a corresponding impairment of movement. On percussion the note is dull, even though cavities are present ; but when the cavity is large a hyper-resonant note is obtained. If there is a large cavity in free communication with the bronchial tube, and the patient's mouth is open, percussion will often elicit the *cracked pot sound*, or *bruit de pot fêlé*, which is somewhat like the sound resembling the clink of coins produced by striking the two clasped and hollowed hands upon the knee. There are two elements in its formation : (1) the presence of a cavity filled with air ; (2) the rapid passage of the air out through a narrow opening on percussion. On auscultation over cavities one may obtain bronchial, cavernous, or amphoric breathing, according to the varying degree of excavation and fibrosis around. It is only truly amphoric when the cavity is large. Bronchophony and pectoriloquy will also be found. Crackling râles of large size and *metallic tinkling* are heard over cavities. The auscultatory sounds are best brought out on deep inspiration or on coughing, when sometimes the sound of *post-tussive suction* may be heard. A cavity probably does not give distinctive signs as compared with consolidation, unless it has reached at least the size of a walnut. At the same time it must be pointed out that a cavity has been found *post-mortem* when there were no signs of it during life.

Circulatory System. The heart becomes smaller in chronic phthisis, as has been shown by X-ray measurements of its width carried out by means of the ortho-diagraph. The principal factor that causes this is presumably the chronic under-exercise ; it is a disuse atrophy.

General Symptoms. *Pyrexia.* From the earliest days of phthisis fever may be present, but it generally bears some relation to the activity of tuberculous processes in the lung, so that, if the mischief becomes inactive from time to time, the fever may for a corresponding time be absent ; but it is often present continuously for months. The temperature is commonly higher in the evening than in the morning, and is either remittent or intermittent in type. The higher degrees of fever are accompanied with the discomfort and malaise common in pyrexia. There are, especially in the advanced stages of the disease, profuse sweats as the temperature falls, and occasionally there is slight chill before the sweating. Actual rigors, however, are exceptional, and the most common event is for the patient to sleep more or less quietly in the early part of the night, so far as the cough will let him, and to wake up in the early morning to find himself drenched with perspiration. Some night sweating is not uncommon even in early stages.

Loss of Flesh and Strength. Emaciation is the rule in phthisis ; it may be one of the earliest symptoms, and may give a note of warning when the cough has been thought to be a mere bronchial catarrh ; towards the end of a chronic case the emaciation is extreme. Exceptionally, nutrition is maintained fairly well even when the physical signs show that there is a considerable and even apparently active lesion. The muscular power is soon enfeebled, and the patients lose

energy, becoming languid and unfit for prolonged exertion, whether of mind or body. The mental condition in many patients, however, is one of great hope and confidence; even when helpless in bed they often fail to realise how ill they are, and look for complete recovery could they but once get rid of the cough.

Anæmia is a frequent symptom, both in the early and late stages, and is intensified if there has been loss of blood from hæmoptysis.

Cyanosis. The face may be livid, especially in acute cases involving a large area of lung, so that the oxygenation of the arterial blood is imperfect. In chronic cases in which the right side of the heart has become somewhat dilated there is more obvious cyanosis, which is due chiefly to retardation of the venous circulation, so that more oxygen is removed from the systemic blood in the capillaries than usual.

Clubbing of the fingers is a common feature of phthisis, though not peculiar to it. The appearance is more pronounced on account of the wasting of the rest of the finger. The same change may be seen in the toes. (See Hypertrophic Pulmonary Osteo-arthritis.)

Dyspeptic Symptoms, such as anorexia, nausea, and vomiting, may occur at any time during the course of the disease. In the last stages sickness or loathing for food is so marked that it is one of the chief difficulties of doctor and nurse to get the patient to take anything at all. *Diarrhœa* is common in late stages; it may be due simply to catarrhal condition, to tuberculous ulceration of the ileum, or to lardaceous disease. The stools are variable, sometimes yellow in colour, undigested, and containing a little mucus or blood. *Peritonitis* is very rarely the result of a tuberculous ulcer. More often it is due to tubercles in the peritoneum, but it is not a common complication.

As well as the symptoms detailed above, symptoms may arise from the deposit of tubercle in other parts of the body, as described in the section on morbid anatomy. Of these, *laryngeal tuberculosis* is the commonest. In addition, there may be various septic complications, such as furuncles, bedsores, etc., in the later stages, and *femoral venous thrombosis*, which is more common on the left side.

Other Forms of Pulmonary Tuberculosis. *Pneumonic Phthisis (Scrofulous Pneumonia).* This begins very much like an attack of acute pneumonia, with pain in one side, high fever, chills, and night sweats, cough and expectoration. The physical signs also are those of pneumonia; but they are most marked at the apex, and spread downwards. Dulness, bronchial breathing, and bronchophony are accompanied by coarse mucous râles, consonating râles, and loud clicks. Often the condition is much more marked in one lung than in the other. The mischief extends rapidly: the pyrexia is severe, there are profuse sweats, appetite is entirely lost, and prostration becomes extreme. The indications that the lung is breaking down are more and more marked; the temperature assumes an intermittent type; the sputum is purulent, and contains *débris* of lung tissue. The illness is often fatal in the course of from five to twelve weeks, either by exhaustion or by hæmoptysis, which is always abundant if it occurs at all.

Hilum Phthisis. This is a chronic form of disease. The patient, usually a child, sometimes an adult, complains constantly of a tired feeling. The temperature is often slightly raised, being perhaps 99° F. in the morning and 100° F. in the evening (rectal). There is an impaired note over the root of the lung behind, on one or both sides, between the vertebral borders of the scapulæ, and Krönig's isthmus may be diminished. Râles are seldom heard. In adults there may be no alteration at all in the percussion note. In contrast to these very indefinite physical signs, the X-rays show increase in the normal root shadows, probably due to lymphatic infiltration, and an extensive fine mottling all over the lungs. It is only when the process, which is at first central, reaches the surface, that râles may be heard over the chest in various situations, particularly over the outer surfaces of the lungs. *

Fibroid Phthisis. This is a very chronic form of apical phthisis, often affecting one lung only. Clinically the case is distinguished by the evidences of contraction of the diseased lung; the chest is sunken; the heart is displaced to the affected side; the opposite lung may extend its resonant area in the same direction; the spleen and stomach if the left lung is diseased, or the liver if the right, may be drawn far up into the chest. The physical signs of cavities are chiefly at the apex, as in other cases of phthisis; but impaired resonance, bronchial breathing, and bronchophony are perhaps present over the whole of the affected lung. If the other side is involved, it is only at the apex. There is often not much cough or expectoration; there is no sweating, and the temperature is normal. In the later stages there may be failure of the right side of the heart, with shortness of breath, dropsy and cyanosis.

Diagnosis of Phthisis. In advanced cases the symptoms and physical signs make the diagnosis obvious. Except in the earliest stages, and in periods of quiescence or arrest, the sputum will show *tubercle bacilli*. For their detection they require to be stained, and to be submitted to a microscopic power of 350 or 400 diameters. The Ziehl-Neelsen method of staining is now commonly employed. A cover glass is smeared over with a thin layer of sputum, which is dried by gently warming and then fixed by passing the slide three times through the flame of a spirit lamp. A solution of 1 part of fuchsin in 10 parts absolute alcohol is added to 100 parts of a 5 per cent. aqueous solution of phenol. This is heated till the steam rises; and the cover glass is floated on it, film downwards, for three or four minutes, rinsed in water, and immersed in a 20 per cent. solution of sulphuric acid until it is decolorised. It is then washed in water, and counter-stained by means of a nearly saturated watery solution of methylene blue, again washed quickly in water, dried, and mounted in xylol balsam. The sputum may also be injected into a guinea-pig for diagnostic purposes, and the animal is examined for miliary tuberculosis after six weeks.

The fragments of *elastic tissue*, which are present with sputum in the later stages, may be seen with the microscope either by teasing out the little rough nodules which are sometimes found, or by boiling the sputum in liquor sodæ for twenty minutes, and examining the sediment. Elastic tissue is found in any case where there is active destruction of lung tissue.

It is much more difficult to be certain of the presence of phthisis in its early stages. Apart from the more obvious symptoms of cough, expectoration and wasting, which may all be absent, valuable indications are obtained from (1) a feeling of tiredness complained of by the patient; (2) changes in the rectal temperature: in very early cases the rectal temperature in the early morning is lower than that of the average normal subject, *i.e.* below 97° F. Later on, at 7 a.m., it is constantly above 98·4° F., and in the evening above 99·5° F. an hour after exercise. It must be remembered that in women the rectal temperature is normally slightly raised for a week before or occasionally after the beginning of menstruation. (3) There may also be a history of pleurisy.

The first *physical signs* of any value in diagnosis are impaired resonance at one apex with diminished vesicular murmur, or diminished vesicular murmur with râles on inspiration or on coughing. The *Röntgen rays* give valuable help in the diagnosis of phthisis, and there may be typical appearances before there are physical signs (Plate 6, A, 7, pp. 168, 174). There may be early limitation of the movement of one diaphragm.

The various *tuberculides* when recognised on the skin suggest some internal tuberculous lesion (*see later*).

Tuberculin in Diagnosis. The Mantoux test is now universally used. Old tuberculin (Okell, 1930) is concentrated ten times over steam, and is put up fortnightly in strengths of 1 in 10,000, 1,000, 100, 10, using as diluent normal saline containing 0·5 per cent. phenol. 0·1 c.c. of 1 in 10,000 is injected intracutaneously as described on p. 140. A delayed, persistent, inflammatory

response, not reading its maximum until twenty-four or forty-eight hours, indicates tuberculous infection (53). Curiously enough, glycerinated veal peptone broth acts just like tuberculin (54); this is reminiscent of the fact that the antigen for the Wassermann reaction is made from non-syphilitic material. If no reaction is obtained, the next strength is employed, and so on.

Diagnosis by the Complement Fixation Reaction. The use of the Bordet-Gengou reaction for diagnosing tubercle, like the Wassermann reaction for syphilis, has recently given good results according to some workers. An emulsion of living tubercle bacilli is used as antigen. This, when mixed with serum from a tuberculous patient, fixes complement and so prevents the hæmolysis of red cells by a sensitised hæmolytic serum (30).

Before *hæmoptysis* is regarded as indicative of tubercle it must be clearly made out that the blood really comes from the lung, and not from the stomach, nose, or teeth; the descriptions of a patient are often very unsatisfactory or misleading. Blood from the lungs should be coughed up, and should be bright red and frothy; it is often preceded by a tickling in the throat, and not by the sense of nausea, which is more common with hæmatemesis. Further, if the blood has come from the lungs, the patient will usually spit up blood mixed with sputum for twenty-four or forty-eight hours after the free hæmorrhage has taken place. In *purpura*, blood may be expectorated actually from the lung, but the cause will be readily distinguished by the associated symptoms. Hæmoptysis sometimes occurs in mitral stenosis in young people. Although phthisis, alcoholism, and cirrhosis of the liver are often associated, bleeding from the lungs may occur in the course of *cirrhosis* quite independent of tuberculosis, and it is not infrequent, especially in older people, as the result of abnormally high arterial pressure.

Phthisis is sometimes masked by an intercurrent *bronchitis* or *pneumonia*. The accentuation of the physical signs at one or other apex is important, as well as the history of the illness, hæmoptysis if present, and the detection of bacilli in the sputum. The possible confusion with *bronchiectasis* has been mentioned (see p. 137). *Empyema* is accompanied by fever, sweating and emaciation; and if it bursts through the lung, there will be cough and purulent sputum. The physical signs will usually be at the base.

Prognosis. In scarcely any disease are cases so different as they may be in phthisis. Discovered in its earliest stage, it may be cured so completely that no trace of it can be detected clinically; it may in other cases be fatal in a few months; or it may last ten, twenty, or even fifty years with obvious physical signs and symptoms throughout. The variable elements are the virulence of the infection and the capacity for resistance on the part of the patient, and it is difficult to estimate which will gain the upper hand until the patient has been under observation or treatment for some time. Improvement may occur at once under treatment, or, at any time in the course of the illness, the protective powers of the patient may be so increased as to cause arrest of the process for a long period. And in no case should hasty predictions be made as to when the end will take place. However, certain factors are known to influence the prognosis. Thus the after-histories of phthisis patients who had been discharged from King Edward VII. Sanatorium at Midhurst showed from three to seven years after discharge 15.6 per cent. of deaths in Stage I. (Turban-Gerhardt), 38.0 per cent. in Stage II., and 70.4 per cent. in Stage III. When tuberculous laryngitis was also present the figures were 42.9, 63.3, and 78.3 per cent. respectively. This complication made the prognosis much worse, especially in the early stages (5). The presence of other complications is also unfavourable. The prognosis is much better if as the result of treatment either there is no sputum or tubercle bacilli cannot be found in it. The prognosis also depends on the amount of care that the patient can take of himself after discharge. It is in general much worse in the case of the industrial classes than in the well-to-do.

Pregnancy has an unfavourable influence on the disease, a fact which is first noticed after the confinement.

Prevention. Fresh air and good food, as recommended for a patient with phthisis, are advisable for children born of phthisical parents. It is by such means that they can best increase the resistance of their tissues against the bacillus. Phthisical persons about to marry should be informed of the risk that their offspring may develop the disease. There is also a definite risk to the healthy partner from infection. With a phthisical patient living in a house, the danger of infection to the other healthy occupants must be guarded against. The patient should sleep in a room by himself. Underclothes and bed linen should be scalded before being washed. There should be ample ventilation in the house. The sputa should in all cases be ejected into antiseptic fluid (5 per cent. carbolic acid solution), and they should finally be rendered innocuous by exposure to boiling water for ten minutes. Tuberculous mothers should not suckle their infants.

Treatment. The most important treatment for an early case is absolute rest until there is no longer any pyrexia, and for chronic cases one day in bed every week is a golden rule. The other requisites are fresh air (*see* p. 5) and plenty of good food. The patient should as far as possible lead an easy life, free from care. In a woman pregnancy should not be permitted, and should be terminated at an early stage if it has begun.

Treatment with the above objects should be taken *as soon as possible* after the evidence of tuberculous infection is confirmed. The methods available may be divided into two groups: *general*, namely, sanatorium treatment with or without change of climate; *specific*, namely, tuberculin treatment, artificial pneumothorax, and sanocrysin. Symptomatic treatment must also be carried out as required.

Sanatorium Treatment. The first object of sanatorium treatment is to teach patients enough about the disease, so that they may live the rest of their lives under conditions favourable to recovery. The second object is to provide for a minimum period of three months, which however ought to be considerably longer, conditions which favour the beginning of their recovery. Patients should not be kept too warm, since cold stimulates metabolism; they live night and day practically in the open air, either in the open or in shelters screening the patient from the wind and rain. The bedrooms and day rooms are thoroughly ventilated, and the rooms are constructed so as to prevent any accumulation of dust. The patients are well fed, having three meals daily of plain but varied food, while care is taken to see that they eat a sufficient quantity of it by weighing any remains after the meal. Exercise is only permissible when the morning temperature is normal, and the evening temperature not above 99.5° (rectal); the exercise will probably raise the temperature for a time; if it does not fall to a normal value after an hour's rest, the exercise should be stopped. The patient begins by taking a slow walk, and the amount of exercise is gradually increased. In any case, he rests one hour before meals and one hour after; and violent exercise and indulgence in exciting games or recreations are prohibited. The clothing of the patient must be suited to the temperature of the air. Treatment on this system has benefited many patients temporarily, but it must be submitted to for very much longer than the period of three months for which it is sometimes prescribed. In fact, a carefully controlled series of results among poorer class patients showed that three months' sanatorium treatment was not at all beneficial, presumably because in his normal surroundings the patient had become more or less adapted mentally and physically to fight the disease, but after a stay in a sanatorium he lost this adaptation and did not regain it on going back to his ordinary surroundings and work (Ward). At the same time a short stay will be of value to teach the patient the principles of his treatment, in order that he may at his own home carry them out as far as circumstances will.

permit. In particular, rest, ventilation, the collection and destruction of sputum and plenty of nourishing food should be insisted upon, and the patients should learn how to take their own temperatures and stay in bed so long as it is raised. In this connection the tuberculosis dispensaries are valuable.

A development of the sanatorium is the tuberculosis *colony*, where patients can live with their families more or less permanently under favourable conditions in the country, following an occupation that partly covers the cost of the treatment (31).

Change of Climate. The places usually selected are South Africa, New Zealand, high altitudes in Switzerland or the Tatra, at places such as Davos, Montana, and Maloja, or the English east coast. The physiological effects of a mountain station, with its relatively low oxygen pressure in the atmosphere, are unique (55), and the benefit obtained is doubtless attributable to them, in particular the stimulating effect on the blood-forming organs, which causes polycythæmia and increase of hæmoglobin in the blood (*see p. 5*). A prolonged stay is often desirable, and it is safer to spend some time beforehand at an intermediate station, such as Bâle. The patient may in any of these places obtain a dry, cool, and bracing air, which he can enjoy for several hours daily outside the house, without the risk of catching cold; and he may spend the whole of the winter, avoiding the cold, damp, and fog of that season in the greater part of England, and returning to his home in the summer, when the weather is more tolerable. With the advent of winter he must again seek the climate which he has found suitable. A dry climate is especially desirable for phthisis patients who have a secondary bronchitic infection. In more advanced cases milder climates may be beneficial, such as that of the Riviera or the English south coast. "Sun-bathing," or heliotherapy, or treatment with ultra-violet light, such as is carried out in surgical tuberculosis, is not usually advisable, since it may cause hæmoptysis from congestion of the lungs. Such is the Swiss experience; but it may, perhaps, be tolerated better in this country. It should only be very slowly begun by gradually increasing the surface exposed, beginning with the extremities. Sunburn must be avoided. The aim should be to produce an erythema, which is followed by pigmentation. Where the disease is active, with slight fever on exertion, hæmoptyses, etc., heliotherapy should not be used (32).

Tuberculin Treatment. This aims at immunising the body against tuberculous infection by the production of anti-bodies. Koch's new tuberculin, or "T.R." (tuberculin Ruckstand)—an emulsion of triturated human bacilli—is perhaps the tuberculin most generally employed. The present practice with regard to the dosage is to keep it just below the point at which a reaction is obtained. It should only be employed for afebrile cases, and the temperature should be carefully observed all through the treatment as a test of the reaction. It is safer to give a very small dose at first, such as .001 c.mm. of whatever preparation is used, double this quantity, .002 c.mm., in three or four days, double this again, or .004 c.mm., after a similar period, and so at similar intervals, or twice a week, until a slight reaction, either local or general, is observed, namely, some thickening at the site of injection, or fever, headache, malaise, etc. These symptoms generally occur within twenty-four hours and subside in about the same time. After three or four days again the last dose may be repeated, when the reaction, if it occurs, will be less, and soon the same dose fails to produce any reaction at all; that is, tolerance to that quantity is established. The dose should now be increased by much smaller additions every half-week until a reaction again occurs, and so on. The duration of the treatment is from six months to eighteen months or two years. A tuberculin made by Beraneck is injected intracutaneously. Some results have been published of the use of a vaccine made from tubercle bacilli after removal of their fatty envelope (34).

Artificial Pneumothorax. This treatment was described in 1821 by Carson, of Liverpool; but it is only within the last few years that it has been widely adopted.

One reason that may prevent tuberculosis of the lungs from healing is that the tissue is kept expanded by the negative pressure in the thorax, and any cavities that form cannot close up. If air is injected into the thoracic cavity, the lung will collapse; it is also congested, which may help the healing process (65).

The operation is especially suitable in cases in which one lung is extensively diseased and the other is relatively sound. In the past it has been used chiefly for advanced cases, but the tendency at present is to use it more widely; in fact, for any case of one-sided disease where the process is extending. There is statistical evidence that the treatment is beneficial (Saugman). Hæmoptysis is a special indication for immediate induction of a pneumothorax on the side of the hæmorrhage. The treatment is illustrated in Plate 6.

The apparatus consists essentially of a trocar and cannula connected on the one hand with a water manometer, and on the other with a receiver filled with air, so that a measured quantity can be passed into the chest. The skin and deeper tissues are anæsthetised with 0.5 per cent. novocaine. The puncture is made either directly or after a slight incision through the skin; and the fact that the needle is in the pleural cavity is recognised by the oscillations of the manometer fluid, which, of course, shows a negative pressure. These oscillations should be from 4 to 6 cms. of water; and if the oscillations are no more than 1 or 2 cms., the needle is probably not in the pleura. When it is certain that the needle is in the pleural cavity, the air is driven in to the extent of 300 c.c. to 500 c.c., or until the manometer oscillates about the zero point. After a week more air may be injected.

Refills should be given according to the absorption of the gas, in amounts from 500 to 800 c.c. and at weekly or fortnightly intervals to begin with, though later on the intervals may be longer, as absorption will be less. They should be continued for three years or longer. The final pressure should never be greater than + 10 cms. of water. The chief accident in the past has been due to air embolism; but this cannot occur if the needle is really in the pleura, and that is the object of having the manometer. Quite rarely unpleasant effects are noticed which are ascribed to the pleural reflex, viz. dyspnoea and palpitations, pallor, and sometimes even loss of consciousness. Sometimes the mediastinum is weak and readily displaced to the opposite side. There may be discomfort and dyspnoea. The condition can easily be diagnosed by X-rays, and here emphasis should be laid on the necessity for screening every case before and throughout the treatment. "Ballooning" of the pleura towards the healthy side sometimes occurs; but if without symptoms, it does not matter. About half the cases develop a clear effusion during treatment. When this begins, treatment should be less active, as the pleura is inflamed. The fluid need not be removed unless the temperature rises, and if removed, it should be replaced by gas. An extension of the pneumothorax treatment suitable for quite early cases consists in admitting into the pleural cavity quite a small volume of air, which is found to collect round the infiltrated part of the lung and cause a partial collapse, while the healthy part remains expanded. A partial pneumothorax can be induced on both sides. Refills must, however, be carried out frequently (35). When a pneumothorax tends to close up in spite of repeated refills, or a tuberculous empyema forms, these are indications for performing oleo-thorax (*see p. 137*).

Where a complete one-sided pneumothorax has been successfully induced, 70 per cent. of the patients have succeeded in getting back to work, but the main difficulty in the treatment is the existence of adhesions, which hinder collapse, and in this case there are only 33 per cent. of successes. It is impossible to diagnose adhesions until the attempt at injection is made. Sometimes they will break down of themselves after repeated refills; but when this is not the case, attempts have been made to divide them. They are localised by introducing a thoracoscope, and they are then cauterised. Unfortunately this kind of operative procedure is apt to lead to tuberculous empyema unless the band is divided right

at the periphery. Various new types of apparatus have recently been described (56, 57).

Two other operations—thoracoplasty and phrenic evulsion—have lately been carried out with success. In *thoracoplasty* the hinder portions of the ribs are removed extra-pleurally from just in front of the angles to as near the transverse processes of the vertebræ as possible. In complete thoracoplasty parts of all ribs are removed from the first to the tenth; but in cases where the disease is limited to the lower lobe a few of the upper ribs may be left intact. Light ether anaesthesia is to be preferred. Forty-five per cent. of cases have become subsequently fit for work after this operation (36). In *phrenic evulsion* the nerve is pulled up from its attachment to the diaphragm on one side through an incision in the neck, so that the diaphragm on that side is raised and paralysed. The operation may be carried out in conjunction with artificial pneumothorax or thoracoplasty, or in basal phthisis, or to prevent cough when due to adhesion of the lung to the diaphragm (37).

Sanocrysin, a thiosulphate of gold and sodium, may be used in the case of patients who have not responded well to other forms of treatment. It is claimed to have in the body a direct destructive effect on tubercle bacilli. It is distributed in sterile ampoules containing weighed quantities from 0.1 to 1.0 gm. The crystals are dissolved in sterile distilled water immediately before use to form a 10 per cent. solution. The solution is injected intravenously, care being taken to avoid leakage into the subcutaneous tissue where it acts as an irritant. The dose must be adjusted to the body weight of the patient and to the nature of the inflammatory change in the lungs. In cases where the disease has become chronic, and the lesions are surrounded by fibrous tissue, a large dose may be given; while in acute cases with recent extension of the disease, a very much smaller dosage is indicated. The urine must be tested for albumen before commencing treatment, and daily throughout the course, and a dose must not be given unless the urine has been free from albumen for forty-eight hours. The initial dose will be from 0.1 to 0.5 gm., according to the weight of the patient and the character of the lesions. There may be a reaction in the form of increased pyrexia, vomiting, diarrhoea or exanthematous rashes on the skin. As soon as the reaction has subsided, or if there be none, after forty-eight hours, the second dose is given, it being 50 per cent. larger than the first. After this a further dose is administered every seventh day, the amount being increased up to 1 gm. if the patient can stand it. The total quantity for the course is 8 to 10 gm. for a patient of 10 stone, and proportionately less for those who are lighter.

Symptomatic Treatment. During treatment in a sanatorium drugs are avoided as much as possible, and it is generally found that the symptoms disappear with the improvement of the patient. It is in all cases essential that the digestion should not be upset by the medicines administered.

Cough. The rapid diminution of cough has been constantly observed in the open-air treatment. The patient should resist coughing as far as possible. If it is preceded by a tickle in the throat, painting the lingual tonsil with iodine may be effective. Otherwise it may be treated as described under Bronchitis.

Night Sweating. This can be generally checked by 1 minim of liq. atropinæ sulph. given in a little water at night, or 2 or 3 grains of oxide of zinc in a pill, with $\frac{1}{8}$ grain of extract of belladonna. Arseniate of iron ($\frac{1}{5}$ grain), or picrotoxine ($\frac{1}{30}$ grain), or tincture of nux vomica may also be used. Night sweating usually means too warm clothing at night or excessive auto-inoculation by the patient with his own toxins—too much exercise, for instance—and reflects on the management of the case by the physician.

Hæmoptysis. The patient should be kept in bed in the semi-recumbent posture; but he should be allowed to change his position when he likes. The most effective hæmostatic is the slow intravenous injection of 20 c.c. of a 15 per cent. solution of calcium chloride. A simple plan is to give 5 to 15 grammes of sodium

chloride by mouth. Sodium bromide may be substituted if the patient is nervous. Bleeding often ceases after inhalation of a few drops of amyl nitrite. In some dangerous cases of hæmoptysis, the induction of pneumothorax has been successful. Hypodermic emetine injections have been successful when the bleeding is slight and continuous (Flandin). The traditional method of treatment is to place an ice-bag on the chest and inject morphia; but this has the disadvantage that the blood is kept stagnating in the lungs and so helps to cause an acute spread of the tuberculous process. It has been found that hæmoptysis is largely independent of the patient's movements (38).

Diarrhœa. For this one must carefully regulate the diet, and use the vegetable astringents, mineral acids, opium, sulphate of copper in $\frac{1}{4}$ -grain doses, or carbonate of bismuth.

Pleuritic Pains are frequent, and are often relieved by antiphlogistine or thermogene wool or by painting the surface of the chest with tincture of iodine. Anodynes internally may be necessary. Many believe that pleuritic effusion delays the progress of the disease in the corresponding lung, and postpone tapping until pressure is extreme. An empyema requiring evacuation may be aspirated.

Excessive Expectorations. This condition may be treated by antiseptic inhalation and expectorants as described under Bronchitis. Drainage with the head down and feet raised may be useful (*see p. 137*).

SYPHILIS OF THE LUNG

Apart from the ulcerations of the bronchi, with resulting stenosis, which have been shown to be due to syphilis and may be diagnosed by bronchoscopy (64), the lung tissue itself may exhibit the effects of the disease in various forms. One is that of the ordinary *gumma*, which is extremely rare in adults, though more common in infants, and gives rise to no recognisable clinical symptoms. Another is the so-called *white pneumonia* of syphilitic infants. The lungs are enlarged, white, dense, and firm; their section is smooth and opaque; they are sometimes resistant, at others easily broken down. The microscope shows a diffuse cellular inflammation of the lung, with thickening of the alveolar walls, and desquamation and fatty degeneration of the pulmonary epithelium. This condition may affect the whole lung, or one part may be uniformly altered, while the other contains only isolated areas. In another variety the alveoli are lined by cubical epithelium, and the connective tissue is replaced by a fibrous stroma infiltrated with cells from the cubical alveolar epithelium. Spirochætes have been found in these cases. As these lesions are found chiefly in still-born children, they have but little clinical importance.

POISONING BY IRRITANT GASES

Poisonous gases used first of all by the Germans in 1915 during the war were (1) *suffocative*, such as chlorine, phosgene, and chloropicrin. These act chiefly on the lung alveoli, causing acute œdema, thrombosis of the capillaries, and disruptive emphysema. In patients who recovered, the œdema fluid disappeared in a few days; but bronchitis and broncho-pneumonia often came on, and emphysema persisted; (2) *lachrymatory* gases—also used in shells, *e.g.* xylyl bromide and chloropicrin; (3) "*mustard*" gas—really an oily liquid which is scattered on the ground or on to the clothes and slowly evaporates. Nothing was usually noticed for some hours except a faint smell of mustard. There then developed severe conjunctivitis, vomiting with epigastric pain, widespread erythema of the skin with vesication leading to severe burns and inflammation of the mucous membrane of the respiratory tract, which caused the most dangerous symptoms. The whole surface became ulcerated and covered with a fibrinous

membrane, it was secondarily infected, and if death did not come on at once broncho-pneumonia supervened.

Later Effects. Many patients who have been gassed develop the "effort syndrome" (*see later*). The following symptoms have been observed, shortness of breath on exertion (70), persistent cough with sputum (54), pain or tightness across the chest (25), palpitation and occasional giddiness (14), morning vomiting or nausea (12), headache (9), neurasthenic symptoms (7), soreness of eyes (5). The blood may show polycythæmia. In this connection Haldane, Meakins and Priestley have observed that these patients sometimes lose the power of breathing deeply, and can only take rapid *shallow* respirations after exercise. They believe that these patients suffer from want of oxygen because the ventilation of the deeper alveoli is defective, so that the blood from these parts is imperfectly aerated. Treatment in an oxygen chamber relieves the symptoms more or less permanently, and the polycythæmia diminishes (Hunt and Dufton).

Various pulmonary sequels to mustard gas poisoning have been described, many of them being of a relapsing character, *i.e.* bronchitis, emphysema, asthma, œdema, pulmonary abscesses, and "pseudo-tuberculosis" with wasting, fever, bronchitis and apical râles, but with no tubercle bacilli in the sputum. There is fibrosis of the lung. These conditions are due to secondary infection after the injury due to the gas. Finally, true tuberculosis of the lungs may be found, probably in those cases where the disease has been previously arrested.

PULMONARY EMBOLISM AND THROMBOSIS

The nature of embolism and thrombosis is dealt with in the section on Diseases of the Blood Vessels, but the special liabilities of the pulmonary circulation to this accident may here be described.

The pulmonary artery and its branches are in direct communication with the systemic venous trunks through the right ventricle and auricle; and accordingly micro-organisms, particles of coagulated blood, or of any other kind, which become loose in the veins of the body or limbs, must be carried into the right cardiac cavities, and thence into the pulmonary artery, where they will be impacted in a larger or smaller branch according to their size. A large old laminated clot may block one of the main branches. In some cases the embolism is a long thrombus from a medium-sized systemic vein which is folded up in a ball.

Pulmonary thrombosis is commoner than pulmonary embolism, occurring in 85 per cent. of thirty-five consecutive autopsies where these lesions were present. Blood clots are found in the branches of the pulmonary artery in all parts of the lungs and there is evidence of their ante-mortem formation in the commencing organisation of the clot or deposition of pigment. The diagnosis of "pulmonary embolism" or "pulmonary thrombosis" usually implies that there is a serious lesion producing widespread effects in the lungs with urgent symptoms, and placing the patient's life in immediate danger.

Pulmonary embolism and thrombosis may result from thrombosis of the femoral vein, such as occurs in typhoid fever, or phthisis, or fracture of the femur in older persons. They may result from acute infections, such as pneumonia, and from surgical operations which involve an incision of the anterior abdominal wall, especially in older people (39). Micro-organisms have in many cases been found in the clots. The effects of the emboli vary with their size. If one of the main branches of the pulmonary artery is blocked, rapid death is a necessary consequence. When the embolus is smaller there is time for changes to take

(The *italic* numbers in brackets refer to percentage incidence of symptoms in 83 cases in the Oxford area.)

place in the lung, and hyperæmia, petechial hæmorrhages, œdema, and collapse with emphysema around it, are found.

In auricular fibrillation which is particularly associated with mitral stenosis small thrombi may form in the auricles owing to their failure to contract, and those from the right side may pass into the lungs and block the smaller arterioles and give rise to local hæmorrhages in the lungs, which are known as *pulmonary infarcts*. Thus a conical portion of the lung wedge-shaped in longitudinal section, its base to the surface of the lung and its apex internally, becomes solid, firm, dark red in colour, and airless; and under the microscope the air vesicles are seen to be filled with red blood corpuscles. The base of the cone bulges on the surface of the lung beyond the surrounding vesicular tissue, and in a short time the surface may present early pleuritic changes. These infarcts are most common in the lower lobes and often involve the lower edge to a considerable extent, when the description of them as conical or wedge-shaped hardly applies. They are commonly about 1 inch in diameter, but sometimes reach a much larger size.

Other bodies may act as emboli besides these venous and cardiac thrombi, namely, particles of growth, and rarely a small hydatid cyst, but quite commonly also pyogenic micro-organisms. When the latter are carried, either alone or with particles of thrombus, into the lung, the conical infarcts soon become abscesses, and are often accompanied by broncho-pneumonia of the adjacent tissue, or by serous, sero-purulent, or purulent pleurisy.

Fat embolism of the pulmonary capillaries is a result of injury, which allows the passage of fat into the vessels. Globules of fat are very commonly seen microscopically in the lung capillaries after death from surgical injuries.

Symptoms. The symptoms of embolism of the pulmonary artery and its main branches vary with the size of the vessel obstructed and the degree of obstruction. When a large thrombus from the femoral vein is impacted in the pulmonary artery or one of its main branches, death may be absolutely sudden; the patient may start up from bed in alarm and fall back dead, or there may be a few minutes' dyspnœa with cyanosis, or, on the other hand, syncope or convulsion. If the obstruction is less complete, the condition may be one of syncope, or syncope with asphyxia, or with rigors, pain in the chest of varying severity, a sense of suffocation, dyspnœa, developing perhaps into Cheyne-Stokes' respiration, and finally slowing down and ceasing. The face may be pale and livid, the jugular veins distended, and the hands cold and clammy. On auscultation the breath sounds are harsh and exaggerated. The onset of symptoms is sudden. In pulmonary thrombosis the symptoms are similar in character, but the onset, rapid as it may be, is gradual.

The symptoms of the occurrence of an infarct will also vary with the size of the vessel obstructed, and the nature of the thrombus or particle impacted. If it is a relatively large vessel, the symptoms may resemble those above described, but will be of less severity. With a sufficiently large infarct there may be breathlessness, palpitation, and even rigor. The extravasation of blood into the lung tissue often reveals itself by the expectoration of blood, or hæmoptysis; and the blood may be in moderate quantity, or in small separate blood sputa or may only render the mucous sputa blood-coloured or rusty. Pain in the side will result from the concomitant pleurisy, and after the event there may be some febrile reaction with or without rigors. Only if the infarct is very large will it give rise to an area of dulness, and suppression of breath sounds; but some crepitation is possible. If an extensive area of dulness is found in a cardiac case in which infarcts are suspected, it must be remembered that the mixed condition of congestion and œdema, known as *red induration* and *brown induration*, is a common result of valvular disease, and often co-exists with infarcts.

Septic infarcts are frequent in pyæmia, and indeed are the characteristic post-mortem lesion of that disease in its acute form. The foci are commonly quite small, and incapable of giving rise to definite physical signs other than some

crepitation. But the pleurisy and effusion which so often accompany them will give the usual signs, and febrile reaction of septic type with rigors and increasing prostration will be present.

Fat embolism, when present in sufficient amount, may be one of the causes of surgical shock, owing to obstruction of the pulmonary circulation. The symptoms are dyspnoea, prostration, red frothy sputum, quick pulse, cyanosis, and râles over the lungs.

Diagnosis. The diagnosis of pulmonary embolism or thrombosis depends very much upon the antecedent data, such as the known existence of venous thrombosis or sepsis, associated possibly with some abdominal operation. The existence of heart disease may suggest pulmonary infarction. Of all the causes of hæmoptysis, heart disease is the next most frequent to pulmonary tuberculosis; the knowledge of this fact goes a long way to a safe diagnosis.

Prevention. It is suggested that after abdominal operations, if there is no peritonitis, and after labour, early movement of the legs and pelvis and massage should be permitted, so as to prevent stagnation, which predisposes to thrombosis. This must be stopped if it is believed that a thrombus has formed. Deep breathing should be carried out systematically to prevent stagnation in the lungs which leads to thrombosis, and to facilitate the venous return from the abdomen. If the patient is blanched blood transfusion should be carried out before operation. The patient should be allowed to drink plenty of water to avoid concentration of the blood.

Treatment. An emergency operation has now been perfected for removing an embolism from the pulmonary artery.

INTRA-THORACIC NEOPLASMS

The commonest causes of intra-thoracic neoplasm are primary carcinoma of the lung and carcinomatous or sarcomatous metastases in the lungs, pleura or bronchial glands, arising from primary growths elsewhere in the body. These are dealt with below. Other pathological conditions that may rarely simulate clinically primary carcinoma of the lung are in the *mediastinum*, growths of the thymus and thyroid (including intra-thoracic goitre), dermoids, teratomas, Hodgkin's disease, mediastinal sarcoma, lympho-sarcoma, primary carcinoma of the œsophagus extending into the lung, in the *pleura* a number of benign tumours, such as fibroma, etc., and endothelioma and sarcoma. In the *lung* benign tumours are very rare; but hydatids, gumma and inflammations may lead to confusion (60).

PRIMARY CARCINOMA OF THE LUNG

Ætiology. Primary carcinoma of the lung occurs at all ages, but most frequently (77)* between forty and seventy. It is four times as common in males as females. Undoubtedly there has been an increase of recent years in its incidence. Since chronic irritation is an established ætiological factor of carcinoma, causes of irritation have been looked for, such as influenza, and following the great epidemic in 1918-19 an increase of carcinoma has certainly been noted; irritation from dust, as in the mines of Saxony, is a possibility; but if inhalation is a cause the right lung should be affected more readily than the left, because the right bronchus is larger and more directly placed; but both lungs are affected about equally. Inhalation of exhaust gases from motor cars, poison war gas, tobacco smoking, road dust, are possible factors (61).

Morbid Anatomy. Primary growths of the lung are classified in three groups according to their origin: (1) from the bronchial epithelium, (2) from the bron-

* The numbers in brackets are percentages taken from an analysis of 139 autopsies at the London Hospital (41).

chial mucous glands, (3) from the lung substance. In the first group the tumour is chiefly localised in one of the larger bronchi, which becomes obstructed; the growth does not spread diffusely but tends to break down and form bronchiectatic cavities. It is columnar-celled. With the second group, which also tends to be localised round the bronchi, there is abundant mucous secretion. However, the cells are so variable in these tumours that this classification is not of much use. More than half of all tumours belong to the "oat cell" type; the cells and nuclei, which stain deeply, are oval and the cytoplasm scanty. Metastases are commonest in the lymph glands, but they occur variously in other organs. Other complications are as follows: pleural effusion (28), viz., purulent (6·5), sanguinous (7), clear (14·5); partial or complete occlusion of a bronchus (56); bronchitis, bronchiectasis, broncho-pneumonia, collapse gangrene, abscess (11·5), emphysema, fibrosis, thrombosis and invasion of pulmonary vessels; pericardial invasion (44·5); invasion of or pressure on œsophagus (16·5); invasion and obstruction of superior vena cava (11·5); thrombosis of large systemic veins (17), which occurred almost as frequently in the lower as in the upper limbs.

Symptoms. *Cough* (66) may be dry to begin with; it may occur in severe paroxysms, or be "brassy" from pressure on trachea or bronchi; it may cause temporary congestion of the veins of the neck. *Sputum* is present in over half the cases, and in most of these there is some *hæmoptysis* (36). *Pain* (64) is variable in intensity; it may be gnawing, stabbing, dragging, or it may be a feeling of pressure or suffocation; it is usually in the chest, but may be felt in neck, abdomen, loins and limbs; it often results from metastases in vertebra or from pressure on nerves. *Wasting* (52) may be associated with malaise, weakness and pallor, but patients are usually not anæmic. *Dyspnœa* (50), apart from breathlessness on exertion, is often a late symptom, unless there is a pleural effusion; it may occur in paroxysms and there may be inspiratory stridor. In one case the CO_2 pressure in the arterial blood was increased and the oxygen saturation diminished, showing that there was obstruction to the interchange of gases in the lung (7). *Pyrexia* (39) often resembles the hectic temperature of phthisis, and it may be associated with chills and *night sweats* (17). *Tachycardia* may be present without temperature (19). *Secondary deposits* are sometimes found clinically (24); and other symptoms are *cyanosis* (21), which is often associated with *dilated veins* (19·5), and which may be seen in head and neck, upper limbs, thorax and abdomen, and are important because they show that there is obstruction in the mediastinum, with the result that the blood finds its way to the heart, by anastomoses under the skin between branches of the intercostal and the abdominal veins. Even with this compensation, the venous current may be much obstructed, and, on stooping down or making any exertion, the face becomes still more congested and cyanosed. In obstruction of the superior vena cava the flow of blood on the surface is entirely downwards, and in obstruction of the inferior cava it is upwards. This last, however, rarely results from intra-thoracic tumour, although it is possible for the malignant growth to reach the inferior cava, just above the diaphragm. *Œdema* (18) is often a late sign and associated with cyanosis and dilated veins; œdema of the head and neck and either arm is very characteristic; it may be transitory, being brought on by exertion or stooping or by cough, and may be associated with a sense of suffocation. There are *laryngeal paralysis* (17); *dysphagia* (11); *vomiting* (11); *clubbing of the fingers* (6·5), but this figure is probably too low; *headache* and *vertigo*, inequality of the pupils and other signs of excitation or paralysis of the sympathetic (*q.v.*). *Arteries* often maintain their course through a tumour unmolested. They are sometimes compressed, with the effect of weakening or obliterating the peripheral pulse.

The *physical signs* are very variable, depending on the position and size of growth, and on the presence of complications. At first they may be only those of obstruction of a bronchus, already described, often accompanied by stridor.

As the size of the tumour increases, with deposits not only in the bronchial glands but spreading out into the lung, there is impairment on percussion chiefly in front of the chest in the upper part, but not reaching up to the apex ; there may be bronchial breathing over this area, increased T.V.F. and bronchophony, or either breath sounds, T.V.F. and voice sounds may be absent. The same physical signs may be present at one base behind if the growth extends downwards. The physical signs of the various complications may be present.

Diagnosis. Some cases may run their course without any thoracic symptoms at all. There is a small *cerebral* group of cases due to metastases which resemble cerebral tumour, meningitis, encephalitis, etc., and a *spinal* group which may be diagnosed as myelitis, spinal caries or lumbago, and a group with acute abdominal symptoms. The stridor produced by compression of a bronchus may be mistaken for the rhonchus of *bronchitis*. The former is constant in time and position ; the latter is variable, and changes from place to place within a few hours, or disappears at intervals. Where the growth produces intra-thoracic complications, such as mediastinal pleurisy, effusion, empysema, bronchitis, bronchiectasis, broncho-pneumonia, these may be diagnosed without realising that growth is the primary cause if the characteristic symptoms such as congestion of veins and local œdema are absent. Phthisis and pneumothorax must also be differentiated. A rapidly recurring sterile pleural effusion after paracentesis will suggest carcinoma, especially if it is bloodstained, though it must be reiterated that tubercle is the commonest cause of a bloodstained effusion. Cytological examination is usually of no help. On the other hand, growth may be suspected in a middle-aged patient, when the signs are those of fluid, but no fluid is obtained on exploring the chest. Carcinoma of the lung is readily confounded with an *aortic aneurysm*, and, apart from the well-known physical signs of aneurysm, X-ray examination provides the most certain means of differential diagnosis in most cases. An aneurysm has a clearly defined edge, which shows expansile pulsation ; but pulsation may be seen with a growth adherent to the aorta. The shadow of an irregularly infiltrating neoplasm gradually merges itself into the surrounding lung, and no true edge can be seen at all. Examination after lipiodol administration may show obstruction of a bronchus. Bronchoscopy is of great value ; a piece of growth is removed for diagnosis histologically. Temporary relief may be obtained by dilating a stricture and allowing pent-up secretions to escape. X-ray examination after pneumothorax with removal of an effusion when present will be of special value in diagnosing pleural growths. Thoracoscopy is also used (Plate 2, B, p. 137).

Treatment. When the growth is accessible to bronchoscopy the treatment has been revolutionised, since it is possible to implant radon seeds at periodical intervals. The operation of lobectomy is also used

SECONDARY DEPOSITS IN THE LUNGS

Symptoms. When the lung is the seat of numerous nodules of growth, scattered indiscriminately through it, the patient suffers at first, at any rate, but little discomfort, and there are no physical signs unless pressure is exerted on a bronchus. In the later stages there will be dyspnœa, rapid breathing, lividity, frequent cough, and mucous expectoration ; and on auscultation numerous rhonchi and râles are heard over the whole chest. The condition bears some resemblance to miliary tuberculosis, but the temperature may be normal. When the pleura is involved there is commonly an effusion which may contain blood and malignant cells.

Diagnosis. When growth is known to exist in other organs, or when a carcinoma of the breast or of the jaw has been removed by operation, the presence of unaccountable dyspnœa should make one think of its occurrence in the lung ; and in cases where the pulmonary symptoms are most prominent the presence

of large hard glands in the neck, or a tumour of the testis, or a rigid spine from implication of the vertebræ, may sometimes give the required clue. X-rays may show in early cases characteristically rounded opacities in the lungs.

The **prognosis** is bad and the duration of the case is not likely to be longer than a year. The **treatment** must be directed to relieving pain and cough and procuring sleep. Deep X-ray therapy may cause temporary recession of the growth and re-expansion of the lungs (62), or radium may be employed in massive doses. A liquid effusion accompanying the growth may be aspirated, but it will probably return quickly.

PLEURISY AND EMPYEMA

The chief features of pleurisy, or inflammation of the pleural membrane, are either the formation of "lymph" on the pleural surface (dry pleurisy), or the exudation of serous fluid (pleurisy with effusion), or the production of pus (empyema).

Ætiology. In a large number of cases the onset of a dry pleurisy, or pleurisy with effusion, occurs insidiously in apparently healthy persons, and is often attributed to exposure to cold. Among such cases a large proportion, perhaps 50 per cent., are undoubtedly tuberculous in origin. Many have a history of tubercle, or they afterwards die of phthisis or other tuberculous lesions. In many cases also the fluid inoculated into animals produces tuberculosis. Such cases of pleurisy are chronic in their course.

The pleura is subject to what is usually a more acute form of inflammation often leading to empyema as the result of many other infections, especially pneumococcal infections, and those of scarlatina, measles, rheumatic fever, septicæmia, and influenza; pleurisy is also a frequent complication of Bright's disease. In other cases the infection is more directly local, as, for instance, when the pleura is injured by fractured ribs, or when there is an extension to the pleural surface of (1) lesions in the lung, like those of pneumonia, pyæmic abscesses, growth, tubercle, or hæmorrhagic infarcts; (2) lesions of the parietes, such as abscesses, in the axilla, breast, neck, or abdominal cavity.

Pleurisy, pericarditis, and peritonitis may occur together from the same infection, which is in acute cases rheumatic, septic, or pneumococcal, in chronic cases often tuberculous; this is known as *polyorrhomenitis*, or *polyserositis*.

The micro-organisms found in different forms of pleurisy are the following: pneumococcus, streptococcus, staphylococcus, *Bacillus tuberculosis* and *B. typhosus*; more rarely Friedländer's bacillus, *B. coli communis*, *B. diphtheriæ*, *B. influenza*, and *Micrococcus tetragenus*. They may be combined, as, for instance, pneumococcus or tubercle bacillus with streptococci or staphylococci; the last are not commonly found alone. In the sterile sero-fibrinous effusions of tuberculosis, tubercle bacilli are absent; tuberculous purulent effusions are also usually sterile on routine cultivation, and tubercle bacilli are rarely found except after inoculation into a guinea-pig. In purulent effusions of children, pneumococci are mostly found (80 per cent.), and in those of adults streptococci are more common (75 per cent.).

Pathology. *Dry Pleurisy.* The first stage consists of dilatation of the vessels of the pleura, quickly followed by exudation of fluid and migration of some leucocytes. The fluid coagulates and the resulting fibrin mixed with the leucocytes, often called loosely "lymph," is deposited on the free surface. The membrane is at first minutely injected, and very soon the naturally shining surface is rendered dull by the fibrin, which can be detached as an extremely delicate membrane. If the exuded material is more abundant, it forms thick layers, firm or pasty, generally rough on the surface, or villous, or reticular.

Pleurisy with Effusion. In this case an exudation of serous or sero-fibrinous fluid soon follows the production of "lymph" in a dry pleurisy, or if the process is more chronic an exudation of serous fluid occurs without the previous formation of "lymph." The fluid may accumulate to the extent of 2 or 3 pints or more in the pleural cavity. It has a yellow or greenish-yellow colour, a specific gravity of 1,005 to 1,030, often 1,015 to 1,018, and it becomes almost solid on boiling from the albumin it contains. Not infrequently there are a few flakes of fibrin, or a quantity is deposited from the liquid a short time after its removal. The liquid is quite clear, or it is opalescent or turbid from the presence of corpuscles. In acute cases eosinophil or polymorphonuclear cells predominate, in the more chronic cases the cells are relatively few and they are lymphocytes. In acute cases the cells may be in sufficient quantity to form a thick layer at the bottom of the fluid after its removal, and there is every gradation between this and the formation of thick pus. Sometimes the liquid is more or less tinged with blood, proceeding from new-formed vessels in the organising "lymph."

This effusion of fluid is one of the most important results of pleurisy. Confined within the cavity of the pleura, it must displace the lung from its relations to the diaphragm and the wall of the chest, and in proportion as more fluid is effused, the lung becomes collapsed. This is not due to the pressure of the fluid, but to the elasticity of the lung, which naturally favours its retraction; and, indeed, it may be found that even with a considerable quantity of fluid in the chest the pressure is still negative. But, even though this is the case, it may yet be higher than the pressure in the opposite pleura, so that the heart is displaced towards the healthy side. However, in some cases the pressure in the fluid may be greater than atmospheric, especially if it is purulent, and then, besides displacing the heart and mediastinum, it bulges the wall of the thorax outwards, distends the intercostal spaces, and forces downwards the diaphragm with the subjacent liver or spleen. In extreme cases the great vessels may be pressed upon and narrowed (Elliot Smith).

Pleurisy heals, like other inflammatory processes, by organisation of the fibrin covering the two surfaces, *i.e.* the new formation of blood vessels and of fibrous tissue. The effusion, if present, is absorbed in the course of days or weeks, and the lung and the chest wall finally come into contact either by expansion of the former, or by a gradual sinking in of the latter, or by a combination of these processes. In mild cases there may be no evidence in later years that any inflammation has ever occurred. On the other hand, the pleura over the lung may show a patch of thickening and be white in colour, while the surface is smooth and shiny. More often the parietal and visceral pleura have been in contact during organisation, so that they become united by fibrous tissue, which is known as an *adhesion*. Adhesions commonly occur between the lobes of the lungs. The vast majority of elderly people who die show evidence of some previous pleural inflammation. In severe cases the pleura may be greatly thickened, and fibrous tissue may invade the lung, producing fibroid lung.

Empyema. The micro-organisms responsible for empyema or purulent pleurisy have already been enumerated. An empyema may be primary in the sense that it is the first or only inflammation caused by an organism that has entered the body through some portal of entry. Again, it may be associated with disease in the neighbourhood—pneumonia, fractured rib, pulmonary abscess—and, lastly, it may be metastatic from disease elsewhere in the body, as in pyæmia. An empyema, like an abscess elsewhere, always begins with an exudation of clear fluid or of a fluid slightly turbid from leucocytes and flakes of fibrin. The length of this stage is variable; it is sometimes prolonged, as when a tuberculous pleurisy becomes purulent—quite a rare occurrence. In pneumococcal empyema there is less delay before suppuration occurs; when, as is usually the case, the empyema is associated pneumonia, suppuration usually takes place during or after resolution forming a *meta-pneumonic* empyema. In this case

the pneumonia is primary and the invasion of the pleura secondary. In empyema due to the hæmolytic streptococcus suppuration may be delayed or take place quite rapidly, so that when a streptococcal pneumonia is present, the empyema is present simultaneously—it is *syn-pneumonic*. In other cases pus is found on the first occasion that a pleural effusion is suspected.

Sometimes an empyema finds its way through the pleural sac, either perforating the lung, so that the pus is expectorated, or “pointing” in one of the intercostal spaces, often the fifth, and bursting spontaneously. In either case, air may find its way into the pleural cavity, and give rise to *pyo-pneumothorax*. Rarely an empyema opens through or behind the diaphragm into the abdomen. But, if unrecognised or untreated, it may remain a long time without perforating, with incomplete absorption, rendering the patient cachectic, and preparing the way for lardaceous degeneration of the viscera.

Both in serous and purulent effusions, the cavity is occasionally divided into separate spaces by adhesions between the lungs and the parietes. The fluid is then said to be *loculated*, and the condition is of importance when the case is treated surgically.

Symptoms and Physical Signs. *Dry Pleurisy.* The onset of pleurisy is characterised by severe pain, caused or aggravated by the act of breathing. The pain is commonly situated low down at the side of the chest; but it may be anywhere, depending on the position of the inflammation. It is cutting or tearing, and is intensified not only by breathing, but by coughing, sneezing, and every kind of exertion. The patient generally lies on his back or on the healthy side. Acute pleurisy may begin with a chill, and there is mostly some pyrexia, in which the temperature may reach 103° , but is more often 101° or 102° . With it are the usual accompaniments: furred tongue, loss of appetite, and malaise.

On examining the chest some impairment of movement on the affected side and deficiency of vesicular murmur at the painful spot are observed; but the characteristic physical sign is the *pleuritic rub*, or friction sound, which arises by the movement upon one another of the two pleural surfaces, roughened by exudation. The sound varies with the degree of friction. In acute cases the rub may be strictly localised and easily missed; it may even be absent, if the patient is prevented by the severe pain from making the inspiratory movement necessary to produce it. In chronic cases the friction may be so great that it can be felt by the hand placed on the chest, as well as heard with the stethoscope, and is quite painless.

Pleurisy with Effusion and Empyema. When liquid is effused, the two pleural surfaces become separated, the friction sound disappears, the pain diminishes, and symptoms and physical signs occur which are the direct result of the presence of liquid and the compression or displacement of the various organs which it affects. The chief symptom is shortness of breath, especially on exertion, and this dyspnoea is in proportion to the amount of liquid effused. He lies on his back, or on the affected side, to allow the greatest freedom to the healthy side. He may be entirely free from cough, or may have slight cough without expectoration. The pupils are occasionally unequal in pleuritic effusion, that on the affected side being larger.

As in other inflammatory conditions, the temperature is variable. In tuberculous pleurisy, for example, it may be very high, suggesting active disease in the glands of the hilum, perhaps; but usually the rectal temperature may only rise to 100° or 100.5° . In empyema, streptococcal or staphylococcal, it is also variable, but is usually high and intermittent or remittent, often with rigors, and the patient is and feels very ill, as in other acute fevers.

As the fluid usually gravitates to the most dependent part of the chest, there is absolute dulness at the base behind, while vesicular murmur, vocal resonance, and tactile vocal fremitus are much enfeebled, or entirely absent. With a

considerable quantity of fluid the following physical signs are observed: On *inspection* the affected side of the chest is motionless. The heart is displaced: with effusion on the right side, its impulse may be perceived beneath or outside the left nipple; with effusion on the left side, an impulse is often felt in the intercostal spaces to the right of the sternum, generally the third, fourth, and fifth, even as far as the right nipple, and in rare instances beyond it. In cases of clear effusion the circumference of the chest on the affected side is not increased; it may be diminished. In empyema it may be increased and the intercostal spaces, instead of being slightly depressed below the level of the ribs, are filled up (or "obliterated"); there may be slight œdema of the chest wall. The spleen or liver may be displaced downwards. On *percussion* dulness is observed in front, in the axilla, and behind, and is continuous with dulness on the opposite side corresponding to the displaced heart. At the same time on the opposite side of the chest the resonance is not unaffected, for a triangular area of dulness is found of which the apex is close to the spine at about the level of the angle of the scapula, and the base extends from the spine along the lower border of the lung for from 2 to 3 inches (*Grocco's paravertebral triangle*). The explanation is as follows: Normally the expansion of the central part of the lung is only possible because the tension of the posterior mediastinum is increased, which prevents it from being sucked over. This increased tension is due to action of the opposite diaphragm. When this is deficient, as in pleural effusion, the mediastinum gives at each inspiration, so that the central part of the lung on the unaffected side receives less air and the percussion note is impaired. When the liquid is sufficient only to reach above two-thirds the height of the chest, there may be heard the peculiar modification of the percussion note under the clavicle and above the level of dulness, which is known as *Skodaic resonance*, which is due to relaxation of the lung (*see p. 123*). On *auscultation* there is diminution or absence of breath sounds, of vocal resonance, and of tactile vibration over the dull area. At the upper level of the fluid where the lung is relaxed bronchial breathing or compensatory breathing may be heard: bronchophony or *ægophony* may be present. On the opposite side the breath sounds are exaggerated, but over *Grocco's triangle* they are diminished. In extreme cases where the lung is compressed solid, there may be loud bronchial breathing instead of absent breath sounds. Where there is great displacement of the viscera, the disturbance of the respiratory functions may at length be fatal. The patient becomes more and more livid, rhonchi and mucous râles are heard in the hitherto healthy lung, and asphyxia ensues. Sometimes there is sudden syncope, which may reasonably be explained by pressure on the heart and great vessels.

In the case of young children the dulness on percussion is not absolute, and bronchial breathing may be heard all over the dull area, and this may lead to the belief that the lung is solid. The displacement of the heart may help in such a case.

Very rarely the pulsation of the heart (or perhaps the aorta) is communicated to a pleural effusion, either as a shock or wave transmitted to a large serous collection or as a more localised, perhaps visible, pulsation in an empyema, pointing through the chest wall. This is described as *pulsating pleurisy* or *pulsating empyema*.

In the early stage of *interlobar pleurisy* there may be pain, cough, and oppression of breathing, but no distinctive sign. When liquid has collected to the extent of 6 or 7 ounces or more, percussion may give a dull note in the middle zone of the chest, with resonance above and below; and this may be accompanied by râles. Hæmoptysis is a frequent symptom in *interlobar pleurisy* (*Dieulafoy*), and if the fluid is purulent, as it often is, it may open into a bronchus, be coughed up and so heal itself, though occasionally a discharging cavity may remain for months or years.

In *diaphragmatic pleurisy* the effusion is located between the lung and the diaphragm; it is not generally abundant; it is often preceded by severe pain with tenderness on pressing over the insertion of the diaphragm into the tenth rib in front, or on compression of the phrenic nerve in the neck. Dulness, friction sound, and ægophony are absent unless the trouble reaches the main pleural cavity, and thus a small collection of liquid, encysted here, may easily be overlooked.

Similarly a *mediastinal pleurisy* may show few distinctive signs until the collection of liquid is sufficient to press upon the important structures in the middle line of the chest. These signs are dyspnœa, attacks of oppression, wheezing and stridor, dysphagia, a brassy cough, hoarseness of voice, and distension of the veins on the surface of the chest. At the same time there may be tenderness on pressure of the dorsal vertebræ, and there may be paravertebral dulness with weak breath sounds, ægophony and râles. Over the pericardium pleurisy gives rise to so-called *pleuro-pericardial friction* (see p. 127). Mediastinal empyemas are liable to be discharged through the bronchial tubes. The diagnosis will be helped by X-rays, which will show whether the obstructing mass is pulsatile or not.

Diagnosis. In dry pleurisy the pain has to be distinguished from other pains in the chest, the most common of which is *pleurodynia*, or fibrositis. This is increased by movement, but is unaccompanied by fever or by rub. Intercostal *neuralgia* is distinguished by its relation to the nerves, and by the tender points characteristic of neuralgia. Perihepatitis and perisplenitis may give rise to pains aggravated by breathing, for these structures are compressed by the descent of the diaphragm during inspiration.

In the stage of effusion we have to consider, first, whether there is liquid in the pleural cavity, and, secondly, what is the nature of the liquid, whether serum or pus. In acute cases, pleurisy and *pneumonia* are most likely to be confounded together, because in the early stages of pneumonia the breath sounds are often absent. Pleurisy is generally characterised by the absence of tactile vibration and the more absolute percussion dulness; and the larger effusions cause displacement of the heart, which is conclusive. With the X-rays a very dark shadow, whose upper concave margin rises sharply from the spine towards the axilla, is produced by pleural effusion; and the line of the diaphragm is not seen (see Plate 7, B, page 168). The lung above shows a faint darkening from condensation, and there is occasionally a line of demarcation (see Plate 8).

In chronic cases, fluid may be simulated by most *consolidations* of the lung tissue, whether from deposit in its substance or from compression; such are some cases of tuberculous consolidation, fibroid lung, the induration which results from heart disease, growth in the lung, compression from the front by pericardial effusion, and from below by subphrenic abscess and by growth or hydatid of the liver. The physical signs common to these conditions are dulness, loss of breath sounds, of vocal resonance, and of tactile vibration—that is, absence of all evidence of healthy lung—simply because these growths or collections of liquids compress or push up the lung in the same way as a pleural effusion does. Another cause of dulness at the base, frequently mistaken for pleural effusion, is obstruction of one bronchus; but in this case the dulness is not usually so absolute as with pleural effusion. X-ray examination is of particular value in distinguishing subdiaphragmatic tumours, abscesses or cysts from a pleural effusion, because the diaphragm constitutes the upper surface of the former, and is convex, though it may be raised and immobile with respiration. The upper surface of a pleural effusion is concave.

With empyema the patient often has a sallow appearance or even marked anæmia; the temperature has often a hectic type, ranging from 98° or 99° in the morning to 102°, 103°, or 104° in the evening, and with this rigors or profuse sweatings may occur. But the chest may be full of pus when the temperature is quite normal. There is pronounced leucocytosis in empyema. The sudden

occurrence of purulent expectoration in the course of pleurisy is an important indication of an empyema which has ruptured into a bronchus ; and in cases of long duration the ends of the fingers become thickened, or "clubbed." Oedema of the chest wall occurs more frequently in empyema than in serous effusions, but in neither case is it an early sign. The chest wall overlying an empyema may be tender on pressure. In young children, a combination of cough, dyspnoea, vomiting and wasting suggests empyema.

Serum may be present in the pleural cavity from other causes than pleurisy—namely, local and general dropsy. The physical signs are the same, but *hydrothorax*, as the condition is called, generally follows upon disease of the heart, or Bright's disease, or pressure upon vessels by growth in the chest ; and there is an absence of the febrile accompaniments of pleurisy.

In all but acute cases the pitfalls are so numerous in diagnosis that an early appeal should be made to exploration with a suitable needle and syringe. This has the additional advantage of determining, as it alone can, the nature of the fluid, and of affording material for microscopic and bacteriological examination. In passive effusions (hydrothorax) large endothelial cells predominate, but lymphocytes may be present ; in infective forms of pleurisy due to streptococcus or pneumococcus the polymorphonuclear and large mononuclear leucocytes are found in excess ; while in tuberculous pleurisy lymphocytes often predominate, but polymorphonuclear cells are often present as well. Tuberculosis is the commonest cause of a bloodstained effusion, but the latter also occurs with growth.

If organisms cannot be directly cultivated from the pleuritic serum, and tubercle bacilli cannot be found, its tuberculous origin may be demonstrated by the *inoculation* of a guinea-pig.

As indicated in the description of the symptoms of the localised pleurisy, their diagnosis may be very difficult. A mediastinal pleurisy is liable to be confounded with mediastinal growths, whether malignant or lymph-adenomatous ; but the history of the former is usually short, and the onset rapid. Help may in all cases be obtained from the X-rays.

Prognosis. Most cases of pleurisy without effusion, or with a sero-fibrinous effusion, get well either under medicinal treatment or after removing the liquid ; but their subsequent history may be often unfavourable. Empyema is very fatal in children under two years old ; only 25 per cent. recover (40). This is because it is usually only one manifestation of a general pneumococcal infection, which simultaneously causes pneumonia, pericarditis, etc. In older children empyema usually follows pneumonia and there are no other complications, and so the prognosis is good, better even than in adults, and more promising the earlier the pus is evacuated. This is probably because in children the majority of cases are pneumococcal, while in adults more are streptococcal. If a pneumococcal empyema is complicated by pericarditis, which is not infrequently the case, the prognosis is bad ; but cases have recovered.

Treatment. If the pleurisy is tuberculous, the general treatment described under pulmonary tuberculosis should be instituted.

Pain may be alleviated by the application of linseed meal poultices, anti-phlogistin or thermogen wool, and the administration of opium or morphia internally, or morphia subcutaneously. The use of blisters, of leeches, or of cupping over the painful spot, also generally gives relief. The affected side may be strapped, and by this means the respiratory movements are restrained, the pain is allayed, and inflammatory action is probably in some measure checked. An excellent alternative method, devised by Sir Charlton Briscoe, is to fasten a belt* tightly round the chest ; a brass spring is let into the belt on the sound side, so that expansion with inspiration is possible here. The strapping should

* The belt is made by Brice & Evelyn, Wigmore Street, W.1.

be applied in broad strips from the spine to the sternum, alternate strips passing obliquely upwards and obliquely downwards, till the whole side is covered. The patient should be kept at rest. If effusion takes place, anodynes will be less needful, and salines, such as the acetate and citrate of potassium, or of ammonium, may be given for their effect upon the excretions of the skin and kidney, the increase of which will favour absorption of the effused fluid. After a time iodide of potassium, squill, or other diuretics may be added, and it is possible that absorption is increased by counter-irritation, such as may be obtained by painting the tincture or solution of iodine over the affected side.

The most usual practice at present in cases of tuberculous effusions is to remove the fluid only when it is present in excessive amounts. It is believed that moderate quantities may be actually beneficial by compressing the lung and diminishing movement, on the same principle that artificial pneumothorax is beneficial. If the heart is pushed over, or there is absolute dulness over most of one side of the chest, some of the liquid should be removed by a trocar and cannula. The best rule is to allow it to escape until it is under atmospheric pressure, *i.e.* until it no longer runs out of the cannula of its own accord. To save time an aspirator is often used, or the liquid is drained away by syphonage through a flexible tube into a vessel placed on the floor; but it must be remembered that it is easy by such means to remove more liquid than is desirable. A recent method is to replace the fluid by air. Great help in expanding the lung may be obtained by simple breathing exercises. The patient should take deep breaths at frequent intervals, and should also blow out against resistance.

If an exploration by the needle shows that the liquid is purulent (empyema), the surgeon should make a free incision under an anæsthetic, local or general, and resect a piece of rib, and allow the pus to drain away. Children under two do not stand rib resection very well. A cannula may be introduced between the ribs by means of a trocar, and tied in position by tapes round the body. A rubber tube which just fits the cannula is introduced into the empyema cavity and the contents evacuated into a thick-walled conical flask, permanent suction being kept up by means of a filter-pump or other contrivance (41). In cases of neglected empyema of long duration, in spite of free drainage, the cavity continues to secrete pus, and the wound does not close. If this goes on too long, the supervention of lardaceous disease is to be feared. There are three possible methods of procedure: (1) The cavity may be washed out with eusol until the contents are practically sterile as tested bacteriologically. Carrel's method of continuous drainage may be used. The wound may then be allowed to close, so that the patient has permanently a sterile pneumothorax. It is best not to wash out an ordinary acute empyema cavity, as deaths have been reported from *pleural reflex syncope*. This is probably due to vagal inhibition produced by irritation of the inflamed pleura. This danger is not apparently present in chronic cases. (2) A fairly extensive surgical operation may be carried out involving the resection of enough ribs to allow the hand to enter the chest. The thick visceral pleura is peeled off (decortication), and the lung rapidly expands and fills up the cavity. (3) Thoracoplasty (*see p. 175*).

The problem often arises as to whether an operation should be carried out in cases of acute pleural effusion due to the streptococcus, for instance where the fluid is somewhat turbid and contains large numbers of polymorphonuclear cells when examined microscopically. The answer is that rib resection should only be used when actual pus is present, but the turbid fluid may be removed by aspiration if present in large amount. American observations at Camp Lee, Va., showed the advantage of this procedure in empyemas due to the hæmolytic streptococcus. In early cases pneumonia is often present with the pleurisy; further, if resection of a rib is carried out at too early a stage, the operation wound may become infected leading to a septicæmia. The effusion, even though turbid, often clears up without operation. On the other hand, pus may develop

in two or three weeks, and then rib resection should be carried out. During the surgical treatment of an empyema the patient should be supported in every way by good food, fresh, bracing air, and by tonic medicines, such as quinine, iron, and cod-liver oil.

HYDROTHORAX

The term is applied to the collection of fluid in the pleural cavity, not as a result of inflammation, but in consequence of heart disease or Bright's disease, cirrhosis of the liver, or interference with the circulation in the chest by growth. It is, indeed, dropsy of the pleural cavity ; and the liquid contains less albumin and less fibrinogen than are found in pleurisy. Its physical signs are similar to those of pleuritic effusion, but the rub is, of course, absent. Arising, as it often does, from a general or central cause, it is much more often bilateral than pleurisy is ; but occasionally a very large one-sided effusion may be merely dropsy. The recognition of hydrothorax, however, generally depends on the history and the previous existence of the diseases which cause it. When the liquid has been removed, the kind of cellular elements it contains may help the diagnosis, as described under Pleurisy. If acetic acid is added to an inflammatory effusion, a white turbidity is produced. This does not occur with a passive effusion.

Its **Treatment** is mostly of secondary importance, being involved in that of the lesion which causes it. As the liquid is almost certain to recur if removed, paracentesis or aspiration should only be performed when a very large effusion, whether on one side alone or divided between the two, is seriously impeding respiration.

HÆMOTHORAX

By this term is meant the effusion of blood in quantity into the pleural cavity ; it is not used for the merely bloodstained serous effusions so common in pleurisy. Hæmothorax commonly results from wounds, injuries or from rupture of a thoracic aneurysm. In the case of wounds the greatest danger to life is from the blood becoming infected from the outside. It occurs sometimes in tuberculosis of the pleura, or from rupture of a pulmonary vessel into a phthisical cavity and later extravasation into the pleura. Exceptionally it occurs from bursting of an emphysematous bulla (Newton Pitt) ; or from degenerated vessels in association with cirrhosis of the liver, granular kidney, or dilated heart ; or from malignant disease. And sometimes it appears to be primary, and the origin is never explained.

The **Physical Signs** are those of liquid in the pleural cavity. In hæmothorax following wounds the diaphragm on the same side is high and immobile ; the lung is much compressed, and above the fluid it is greatly relaxed, so that Skodaic resonance is especially marked.

The **Diagnosis** will depend, in the case of aneurysm, on the previous history, and on syncope and pallor indicating rapid loss of blood. A hæmothorax may only be discovered on exploration.

Treatment. If the liquid be aspirated, it is very likely to return ; and probably it is better to leave the blood to be absorbed, unless it is causing distress by direct pressure. In the case of wounds a moderate hæmothorax may be aspirated a week after the wound, and it is often an advantage to replace it by oxygen. A septic hæmothorax requires free drainage.

CHYLOTHORAX

Rarely an effusion into the pleural cavity is found to be white and milky, like the fluids sometimes present in the peritoneal cavity. In some cases it is a true *chylothorax*, in others a *chyliform effusion*, in which the milky appearance is not

due to the fatty elements of chyle, but to granules of a lecithin compound (*see* Chylous Ascites). The causes are the same as in the case of the peritoneum. Cases of chylo-hæmothorax have been recorded as a result of injury to the thoracic duct in the chest.

PNEUMOTHORAX

Pathology. The presence of air in the pleural cavity constitutes a *pneumothorax*. If serum is present at the same time, it is a *hydro-pneumothorax*; if pus accompanies the air, a *pyo-pneumothorax*; if blood, a *hæmo-pneumothorax*.

Air may gain an entrance to the pleural cavity—(a) through an opening in the chest wall, (b) through a breach in the surface of the lung, or (c) occasionally from the rupture of some other air-containing viscus in the neighbourhood. (a) A pneumothorax may be brought about by any wound in the side which passes through the whole thickness of the chest wall; it is commonly produced artificially when a piece of rib is resected for empyema (pyo-pneumothorax), or in the treatment of phthisis by inducing artificial pneumothorax. (b) It is produced by a fractured rib puncturing both layers of the pleura, so as to let out air from the lung into the pleural cavity, while the skin remains intact. In nine out of ten cases of pneumothorax occurring spontaneously from rupture of the surface of the lung, the result is due to phthisis when a vomica ulcerates through into the pleural cavity; and less commonly an empyema makes its way through the pleura into the lung, and air passes into the pleural sac, so as to form a pyo-pneumothorax. In acute pneumonia the pleura has been known to rupture, so that air has escaped and a pneumothorax has been formed; and a pyæmic abscess or gangrene of the lung may lead to a similar result, or an emphysematous bulla may burst. Very occasionally a pneumothorax occurs spontaneously from rupture of the lung in quite a healthy person, possibly as the result of some sudden strain. (c) Air may also enter the pleura in consequence of a spinal or mediastinal abscess burrowing into the pleura; and ulcer or carcinoma of the stomach, or carcinoma of the œsophagus, may let in air from the alimentary canal.

A pneumothorax may be described as open, closed, or valvular, according to the condition of the opening which created it.

Open Pneumothorax. When air enters the chest from an external wound, and the wound remains patent, the lung collapses by its own elasticity; and not only the lung of the wounded side, but also the opposite lung, may contract somewhat and draw with it the mediastinum, so that slight lateral displacement of the viscera takes place, just as it does in liquid effusion. The same thing may happen if the pneumothorax results from rupture of a cavity in phthisis, supposing the aperture to remain patent, so as to keep the pleural sac in communication with the bronchial tubes. In both these cases the mean pressure of the air in the pneumothorax is equal to that of the atmosphere.

Closed Pneumothorax. When the aperture is small it may be quickly closed by lymph; further extravasation is prevented, and the air may then be completely absorbed. This happens in cases of laceration of the pleura by fractured rib, and sometimes in pneumothorax from disease of the lung. In closed pneumothorax there is a slowly progressive absorption of the enclosed air; the pressure is negative, and the displacement of organs is, *cæteris paribus*, less than in open pneumothorax.

Valvular Pneumothorax. A third possibility is that a shred of pleural membrane or lymph hangs over the aperture, so as to form a valve. The air is then drawn into the pleural sac by inspiration, but is unable to escape during expiration; the mean pressure becomes positive—that is, it exceeds the pressure of the atmosphere, and the displacement of viscera and distension of

the chest may be extreme; thus the heart may be pushed far over to the opposite side, and the liver or spleen may be driven down by the flattening or inversion of the diaphragm. A valvular opening may, like others, become closed by adhesions.

The amount of collapse of the lung, and displacement of the viscera, is influenced in different cases by the previous condition of the lung. If the lung is extensively diseased in phthisis, or in great part adherent, the collapse will be less than if the lung is for the most part healthy.

Physical Signs. Resonance depends on the presence of a cavity and of elastic walls capable of vibrating in unison with the air waves (*see* p. 122). The elasticity of the walls depends largely on the pressure of the air inside the cavity. If the pressure is very high, as in a valvular pneumothorax, the note is dull. It may also be dull if the pressure inside is the same as the atmospheric pressure, as occurs after the resection of a rib for empyema. Under favourable conditions of pressure, whether the latter is greater or less than the atmosphere, a tympanitic note is obtained on percussion, and this is accompanied by the *bruit d'airain*, or *bell sound* (*see* pp. 123, 127), and in very favourable circumstances by *metallic tinkling* (*see* p. 126). The dependence of the *bruit d'airain* on the elasticity of the walls of the cavity, which itself is determined by the pressure of the contained air, can be demonstrated by the student to himself as follows: He closes his mouth, blows out his cheeks, lays one coin on the cheek and strikes it with another. A musical sound is obtained if the pressure exerted by the cheeks on the enclosed air is correctly adjusted. Another characteristic sound is due to the dropping of fluid from the upper part of the chest into the liquid below, the noise being reverberated with almost musical quality. The respiratory murmur is often entirely inaudible, or faint amphoric breathing is present. Amphoric breathing may be due to compression of the lung or possibly to an opening leading from a bronchus into the pneumothorax; but a fainter sound may occur even when adhesions have shut off the lung from the pleural cavity. Vocal resonance and tactile vibration are generally much diminished, but bronchophony or pectoriloquy may be present when there is amphoric breathing.

If there is also liquid effusion, it gravitates to the lowest part of the chest under all circumstances. If the patient is recumbent, the posterior part of the chest is dull, and the anterior part is tympanitic; if the patient now sits up, the lower part of the chest, back and front, becomes dull, while the upper part, back and front, is resonant. If *Hippocratic succussion* be employed, a splashing sound will be obtained (*see* p. 126).

The **Symptoms** of pneumothorax are very variable, depending largely upon the amount of antecedent disease. If it supervenes upon a lung extensively diseased, it may add but little to the distress already present; if it occurs in a lung for the most part, or entirely, sound, the symptoms will be pronounced; lastly, if in a case of phthisis with extensive disease on one side pneumothorax occurs on the other side, the result may be quickly fatal. The symptoms in the severe cases are sudden pain with a sense of something giving way internally, then distress of breathing, with more or less collapse, small pulse, lividity, and sweating. The breathing is rapid; the chest is distended on the affected side, and the intercostal spaces are depressed on inspiration.

These troubles may be aggravated until death takes place within a few hours or two or three days, or the first severe symptoms may subside, and comparative ease may follow, but generally with rapid breathing and orthopnoea.

Diagnosis. A resonant note associated with deficient breath sounds or distant bronchial breathing suggests the diagnosis, but without X-rays mistakes are common. X-rays show the transparency due to air in the pleural cavity, the collapsed lung, the depressed diaphragm on the same side, and the displaced heart (*see* Plate 7 B, p. 174). The presence of fluid in a pneumothorax produces a very characteristic X-ray appearance when the patient is examined

in the vertical position, because it is opaque and its upper surface is a horizontal line, while above it there is transparency owing to the air (*see* Plate 9, A). Further, on inclining the body the surface of the fluid still remains horizontal. A *diaphragmatic hernia*, that is, the escape of the stomach or the colon into the thorax through an aperture in the diaphragm, may closely resemble pneumothorax in its physical signs, and it may arise in the same way, from a contusion of the chest. Pneumothorax may also be simulated by an unusually high position of the stomach in the chest in consequence of contraction of the left lung, and by abscess beneath the diaphragm containing air (*subphrenic pneumothorax*, Plate 32, A, p. 407).

Prognosis. The occurrence of spontaneous pneumothorax in phthisis is on the whole, a favourable event, and cases have improved subsequently (*see* Artificial Pneumothorax). In other cases the prognosis is, on the whole, good with suitable treatment, though it depends on the attendant circumstances.

Treatment. This is, in the main, palliative. For the intense pain and distress accompanying the rupture opium or a subcutaneous injection of morphia ($\frac{1}{4}$ to $\frac{1}{2}$ grain) should be administered, and hot poultices and fomentations should be frequently applied. Stimulants, as wine, brandy, or ether, may also be required. In cases of extreme distension it may be desirable to perform paracentesis, a trocar and cannula being inserted between the ribs over the resonant area and the air allowed to escape till atmospheric pressure is reached; the relief is, as a rule, only temporary, and the paracentesis may have to be repeated. Alternatively, in the case of valvular pneumothorax, a steady negative pressure can be applied, using a Sprengel's filter pump (63). If the communication with the lung becomes closed, the air will probably be absorbed; but to facilitate its absorption it may be replaced by oxygen. A simpler plan is to use a high percentage of the oxygen in a tent; the nitrogen diffuses out and the pneumothorax then rapidly disappears. In hydro-pneumothorax the serum may be left alone, or, if present in large amounts, it may be removed by paracentesis. If a pyopneumothorax is producing constitutional symptoms, *i.e.* temperature, rapid pulse, etc., it should be treated like an empyema with rib resection and drainage. Otherwise the liquid may be dealt with like serum.

DIAPHRAGMATIC HERNIA

This condition, which is of rare occurrence, may be mentioned here, because the contents of the thorax are necessarily modified by the invading viscus, and physical signs are produced which may closely resemble those of pneumothorax. In diaphragmatic hernia one or more of the abdominal contents, generally a portion of the stomach, or of the omentum, or of the colon, passes upwards into the thorax through an aperture in the diaphragm. Mostly the aperture is the result of injury, such as a forcible sudden compression of the chest, or it is a congenital defect, or the enlargement of a natural opening. The lesion is more frequent on the left side, and the stomach is commonly the viscus, which passes into the thorax and is drawn upwards in the process (Plate 9, B).

Symptoms. When the diaphragm is ruptured by injury, the early symptoms, such as pain, dyspnoea and collapse, are partly due to the direct effects, and partly to the sudden disturbance of the contents of the thorax with compression of the lung on the same side. Pleurisy and peritonitis may also supervene with the symptoms referable to them. But in many cases the first effect of the injury passes off, and the symptoms are partly pulmonary and partly gastric or gastro-intestinal. The pulmonary symptom is mainly shortness of breath, but it is remarkable how little disturbance may be felt on the side of the chest in some cases. On the side of the abdomen are generally observed indigestion, pains,

flatulence, and perhaps vomiting. These symptoms may come on periodically, being due to distension or kinking of the viscera in their abnormal situation. In a recent case severe symptoms were noticed at periodic intervals, when for some reason the stomach was forced up through the diaphragm compressing the lung.

The physical signs noted in the chest are hyper-resonance in the lower part occupied by the herniated viscus, with loss of breath sounds, gurgling sounds heard on succussion or spontaneously, metallic echo and the *bruit d'airain*. The heart may be displaced if the visceral transfer is considerable.

Subphrenic pneumothorax may also present somewhat similar physical signs. It is more common on the right side, and the liver is depressed by it into the abdomen. The hyper-resonance resulting from it is not likely to rise so high in the chest as in either of the other two cases, and the history will probably assist in the diagnosis (*see* Plate 32, A, *facing* p. 407).

Diagnosis. The diagnosis of diaphragmatic hernia can only be made with any certainty by X-ray examination after an opaque meal (*see* Plate 8, B).

Treatment. Some patients are not very seriously inconvenienced after the first troubles have passed. Surgical treatment involves opening the chest, removing portions of ribs, returning the viscus to the abdomen, and sewing up the diaphragm.

MEDIASTINITIS

Inflammation of the mediastinum may be suppurative or non-suppurative. The former, or *mediastinal abscess*, arises from numerous causes, of which injuries by bullet, stab, or blow, and tuberculosis of the lymphatic glands are the most frequent, while occasionally it follows upon pneumonia, pleurisy, erysipelas, or enteric fever. The abscess may be in the anterior or in the posterior mediastinum, more often in the former. The chief symptoms are sternal pain and pyrexia. Physical signs will only be apparent if the abscess reaches a sufficient size, when there may be dulness, localised tenderness, œdema over the sternum, and ultimately fluctuation at the border of that bone. The pus must be evacuated as soon as possible, and, if necessary, the sternum must be trephined or a portion resected.

Adhesive or non-suppurative mediastinitis may also arise from traumatism and general infectious disease, but its most common associations are pleurisy and rheumatic pericarditis, especially the latter, forming then *mediastinitis fibrosa*. This has been described under Adherent Pericardium.

DISEASES OF THE NOSE, THROAT, AND EAR

(From the Medical Aspect)

THE NOSE

CORYZA

This disease, familiarly known as a “cold in the head,” is a catarrhal inflammation of the mucous membrane of the nose (acute rhinitis), which often involves the pharynx (catarrhal sore throat) and also the conjunctivæ, frontal and other sinuses, and Eustachian tubes, and may spread to the larynx, trachea, and bronchi. It is primarily an infection, which is spread by the inhalation of a spray of saliva from an infected person, emitted during coughing, sneezing, and talking. Sometimes at the end of a period of immunity acquired from the last attack patients may reinfect themselves. The cause of a common cold is a minute “filter-passing” coccoid body, 0.2 to 0.3 micron in diameter, arranged singly, in pairs and in groups, and resembling the virus of poliomyelitis (1). If the normal nose and throat are examined bacteriologically there appear commonly to be zones of living bacteria; *Staphylococcus albus* is present in the anterior nares; the *B. septus*, which is a diphtheroid, grows at the back of the nose. *Micrococcus catarrhalis* predominates in the nasopharynx, and the *Streptococcus viridans* on the tonsils. When the cold begins the *Streptococcus viridans* is commonly the first organism to multiply vigorously—particularly the more haemolytic strains, and tends to overgrow the more normal inhabitants; a little later culture may show activity among one or more secondary invaders, such as Freidlander’s bacillus, the pneumococcus Type 4 and the *Staphylococcus aureus*, any of which may be found located in the sinuses, when there is local suppuration. There tends to be a predominance of one type of organism according to the epidemic and in some epidemics Pfeiffer’s *Bacillus influenzae* is found to the exclusion of all the rest. The chief predisposing cause is congestion and swelling of the nasal mucous membrane. In general this is brought about by a moist atmosphere with the temperature variable, but on the whole cool. It is this latter fact that has given rise to the phrase “catching cold.” It is under such conditions that epidemics occur. Again, the conditions indoors may be responsible; people often sit in a warm stuffy room where the air is stagnant, but where the floor is made cold by draughts. The head is warm, and the feet are chilled. Physiologically the head and nasal mucous membrane should be cool and in fresh moving air, and the feet should be warm (L. Hill).

Symptoms. An attack of sneezing or a raw or rough feeling in the throat and pain on swallowing may be one of the first symptoms; but these may be preceded by a feeling of indisposition, with chilliness, headache, and loss of appetite. The sneezing is soon followed by the discharge of clear mucus from the nose; and there is a feeling of stuffiness in the nose, due to swelling of the mucous membrane and loss of the sense of smell. The soft palate, uvula, pharynx, and tonsils are redder than natural; in more severe cases (*ulcerated sore throat*) superficial abrasions occur on the tonsils, palate, and pharynx, the tongue is furred, and

there is marked constitutional disturbance. At the same time, the eyes are suffused and water freely, there is pain over the eyebrow from implication of the frontal sinus, and there may be deafness from closure of the Eustachian tube. Some febrile reaction is present at the same time. If the catarrh extends to the larynx, the voice is hoarse, and there is constant irritating cough; and its further spread to the lungs will cause the symptoms described below under Bronchitis. Often after one or two days the acute stage subsides, and recovery is complete. On the other hand, the discharge may continue, becoming thicker and more opaque from the presence of pus with the mucus. It may continue thus for a variable period, from two or three days to two or three weeks. During this time the patient is liable to fresh exacerbations of the inflammation.

Such is the typical picture of a coryza; but in other cases the infection may begin as an acute laryngitis or bronchitis and subsequently spread upwards to the throat and nose. The clinical picture in different people is variable; but in the individual person the course of the infection tends to be pretty constant. Thus, in one person a coryza always begins as a pharyngitis, in another as a laryngitis, in another as a bronchitis, and so on. People are thus very prone to suffer from repeated infections which chiefly attack one particular part of the respiratory tract. In those from whom the tonsils have been removed a coryza is more apt to begin as a pharyngitis or laryngitis. After a time recovery may be longer and longer delayed, and a chronic infection may result, taking the form of chronic nasal catarrh, chronic catarrhal laryngitis, chronic bronchitis, etc., depending on the part attacked in the first place.

It must be remembered that acute rhinitis occurs as a specific lesion in some of the infective diseases, such as influenza, measles, diphtheria, congenital syphilis, glanders, and others.

Prevention. A hygienic method of life with plenty of outdoor exercise and a daily cold bath for robust persons, the avoidance of stuffy rooms, and especially of infected persons, are important measures. Personal experience has shown that a treatment devised by W. Glegg for chronic nasal catarrh is of the greatest value. While the patient lies on his back one or two teaspoonfuls of a mixture of paraffinum molle and paraffinum liquidum (1 in 3 or 4) is run down each nostril in turn from a pipette supplied with a rubber bulb. When the mixture is felt in the throat it may be swallowed, or expectorated if it causes looseness of the bowels. This treatment can be carried out once or twice a day, or more often if a cold is threatening. The mixture is also supplied in a collapsible tube and menthol gr. $\frac{1}{2}$ per. oz. may be added, or it may be flavoured with rosettol.

In many cases nasal and bronchial catarrh have been prevented by means of vaccines prepared from bacilli and cocci present in the respiratory passages during epidemics. Autogenous vaccines prepared from cultures of the patient's own organisms in the sputum or obtained by means of sterile swabs from the back of the nose and throat may be injected or added to the stock vaccines. In preparing the vaccines it is important to remember that cultivation and incubation should be carried out *immediately* the material has been obtained. It seems at first sight surprising that vaccines prepared from bacteria should be useful, when the infection is due to a filter-passing organism. It is possible that the causal organism only acts in symbiosis with the secondary invaders, as is the case with hog influenza; so that it is enough to autogenise them.

Treatment. Personal experience has shown that Glegg's treatment may abort the nasal coryza, and in the later stages, when the secretion has become mucopurulent and discharge is frequent, much relief may often be obtained; but it will have no effect on infection which has spread to the larynx and trachea. If the cough be troublesome, a few drops of ipecacuanha wine, with spirits of nitrous ether or compound tincture of camphor will relieve. Steam may be inhaled, impregnated with eucalyptus oil by placing five or six drops of the oil in boiling water in a suitable inhaler.

Follicular Tonsillitis. Apart from the infections just mentioned, inflammation of the lymphoid and follicular substance of the tonsils arises apparently spontaneously and in some persons occurs repeatedly at intervals of months or years.

It is probably due to infection, or to increase of virulence of organisms latent in the crypts, combined with depression of the resisting powers of the individual or his tissues.

Symptoms. The tonsil is red and swollen, and presents several yellow or white prominent spots, which are masses of purulent exudate, exfoliated epithelium, polymorphonuclear leucocytes, lymphocytes and bacteria at the mouths of the crypts; and the surface is covered with more or less mucus. The swelling can be felt externally behind the angle of the jaw. In severer forms the secretion of the crypts is more abundant, and they are distended with large bright white plugs, which may present a close resemblance to the white material of diphtheria. The "follicles" may coalesce to form a patch closely resembling the membrane of diphtheria. Both tonsils are frequently affected. There is moderate constitutional disturbance, furred tongue, feeling of malaise, local discomfort, and pain on swallowing. There is often a considerable rise of temperature. As a rule, the tonsillar cervical glands are enlarged.

Morbid Anatomy. The cells of the parenchyma of the tonsils and of the follicles are increased in number, and very small abscesses may form in the follicles, and burst into the crypts.

Diagnosis. The occasional resemblance to *diphtheria* is most important. Generally the obvious formation of the plug of secretion within a crypt of the tonsil, or the existence of several on each side, serves to distinguish them. A single white patch of some extent, apparently only on the surface, and an extension of this to the soft palate are in favour of diphtheria or Vincent's angina. Bacteriological cultivation should be employed in doubtful cases (see p. 66).

Treatment for pyrexia should be instituted (see p. 20). The tonsils may be painted with astringent or antiseptic solutions, such as Tr. iodi B.P., glycerine of tannic acid, and tincture of perchloride of iron in glycerine (5 drops to 3j). Lozenges of potassium chlorate or rhatany and formalin tablets may also be sucked. Tincture of guaiacum, or tablets of guaiacum, and sodium salicylate are also useful. In severe cases injections of anti-streptococcal serum may be given: anti-scarlatiniform 10 c.c., polyvalent 25 c.c., repeated in two days.

Keratosi Pharyngis is a condition in which small white projections occur at the mouths of the tonsillar crypts and give rise to an appearance similar to that of follicular tonsillitis. It is as a rule symptomless though sometimes a slight sore throat is complained of. It resists all treatment, but disappears spontaneously after persisting for many months.

Peritonsillar Abscess (Quinsy). In this condition suppuration occurs between the capsule of the tonsil and the muscular wall of the tonsillar bed. The exact position of the abscess varies, but it generally occupies the upper two-thirds of that space, pushes the tonsil downwards and inwards, and encroaches on the palatal tissues.

Ætiology. This is most common between the ages of fifteen and twenty-five; some persons are very liable to it, and have it repeatedly. It is due to the spread of tonsil infection beyond the capsule of the tonsil—a peritonsillitis—and suppuration follows.

Symptoms. It may affect one or both tonsils. The tonsil becomes red and swollen to twice its natural size, projecting to the middle line, and pushing the uvula aside; if both tonsils are affected, they may meet in the middle line, driving the uvula forwards; the swelling and redness involve the soft palate, which becomes œdematous for a variable distance forwards. The surface is generally smooth, shining, and deep red or purple in colour. Externally there

is obvious swelling behind the angle of the jaw. The illness often commences with a rigor and sickness, and the constitutional disturbance is considerable. The tongue is thickly furred, appetite is lost, and the temperature rises to 103° or 104°. Swallowing and talking are excessively painful, and saliva and mucous secretion collect in the mouth, and require to be constantly expectorated. In from two to four days suppuration occurs; the tumour, which was at first hard, is now softer, and yields to the finger; or the presence of pus may be detected by placing one finger on the tonsil and another outside behind the angle of the jaw. If left alone, the abscess bursts into the throat, the temperature falls, and recovery quickly takes place in from four to seven days, though convalescence may be protracted for some time longer. Rarely the abscess has burrowed into the neck or chest, or eroded the carotid artery, or caused suffocation by discharging its pus into the larynx.

Diagnosis. Quinsy may resemble *follicular tonsillitis*; it is more often unilateral, the fever is more severe, the redness extends to adjacent parts, secretion does not accumulate in the crypts, and pus may be eventually detected. Sometimes the two occur together.

Treatment. The general treatment for pyrexia is used. Ice often relieves the pain; it should be sucked as well as applied to the throat externally. Salicylate of sodium in 10- to 15-grain doses every three or four hours may be given internally to diminish the acute symptoms. Gargling with hot carbolic acid lotion, 1 per cent., relieves pain. If suppuration has commenced, hot fomentations and poultices probably hasten it. When pus is detected, an incision should be made into the prominent part of the abscess with a bistoury, covered up to the last half-inch with plaster, so as to protect the other parts of the mouth. Injection of anti-streptococcal serum is useful in the early stages.

Chronic Sepsis of the Tonsils. This is of common occurrence in children, and often results in enlargement of the tonsils, which may subside as the patient advances in age. But chronic septic tonsils may be small and buried between the pillars of the fauces. Chronic sepsis may result from previous acute tonsillitis.

Pathology. Enlarged tonsils show hypertrophy of the parenchyma and follicular tissues with more or less accumulation of secretion in the crypts, which are also large.

Chronic infection of the tonsils is of importance, as it may provide a focus from which other parts of the body may be infected through the blood stream. Much of what has been said concerning apical abscesses of the teeth also applies here. Dental sepsis is usually more important in adults, while the tonsils are more important as sources of infection in children. In both cases secondary infection is the more likely to occur because the primary focus is deep-seated. In fact, Gardiner regularly obtained cultivations from the deep aspect of tonsils removed at operation. Acute rheumatism and nephritis may often be secondary to septic tonsils, and they may provide an entrance through which tubercle invades the body: in fact, some enlargements of the tonsil are due to tubercle, and actinomycosis of the tonsil has also been observed.

Symptoms. The tonsils are pale pink, lobulated on the surface, and firm in consistence, and pus or caseous material can be squeezed out on pressing with a spatula. When only of moderate size, they may cause no local symptoms. When the tonsils are large adenoids are as a rule enlarged too, and then nasal respiration may be obstructed. The child breathes with the mouth open, and, the nasal passages being little used, the anterior nares are small and the alæ compressed. Swallowing is laborious and clumsy, and speech is suggestive of something being in the mouth. Hearing is also deficient, from catarrh of the Eustachian tube. Cough, nasal catarrh, restlessness, and headache are other symptoms observed in such cases.

Treatment. Tonsillectomy is the standard treatment, and the relative

rarity nowadays of tuberculous glands in the neck may be due to the frequency with which this operation is carried out. Unless there is a very clear indication, operation is best not carried out much under 10 years, as the loss of the protective function of the tonsils may be serious. Bradley observed at a public school that epidemic catarrhal infection was most severe in boys who had had tonsillectomy. If operation is inadvisable, the secretions or caseous masses may be squeezed, syringed or sucked out of the crypts, and antiseptic lozenges be given.

VINCENT'S ANGINA

This inflammatory condition is found in two forms : (1) ulcerative ; the ulcers are oval in shape and occur typically upon one tonsil, rarely on both, in children on the tongue and cheeks ; ulcerations of the gums round septic teeth are often found to contain Vincent's *Bacillus fusiformis*. (2) pseudo-membranous, resembling diphtheria. It may spread from the tonsil on to the surrounding mucous membrane. Sometimes it does not affect the tonsil, but instead the soft palate or pillars of the fauces. The cervical glands are swollen, and there are difficulty of swallowing and some fever, and the breath is foetid. Usually in eight or ten days the membrane disappears. The fever is but slight, the glands never suppurate and the prognosis is good.

Two organisms are found in these cases : (1) the *Bacillus fusiformis*, which measures from 6μ to 12μ in length, looks like a long thin triangle, occurs in pairs, with the bases contiguous, and is readily seen by dark ground illumination. (2) *Vincent's spirochæte*.

Treatment. The ulcers should be painted daily with a 10 per cent. solution of silver nitrate ; aspirin may be given to relieve pain. Infection of the gums may yield to injections of novarsenobenzol.

PHARYNGEAL TONSILS

This is a mass of lymphoid tissue situated in the naso-pharynx, together with scattered nodules in the mucous membrane of the fossæ of Rosenmüller and of the posterior wall of the pharynx. The mass may be sessile or pedunculated, consisting of finger-like processes, separated by fissures or clefts, analogous to the crypts of the faucial tonsil. It is covered with a layer of columnar ciliated epithelium. Enlargement is common between the third and tenth years of life ; it may follow the infectious diseases of children, and is often associated with attacks of catarrhal rhinitis.

The pathological results of hypertrophy of the pharyngeal tonsil, often called *adenoid growth* or *adenoids*, are important. Chronic catarrh may spread up the Eustachian tube, and cause otitis media, and later chronic inflammation of the mucosa. In the course of the growth of the child occur some of the changes referred to under the head of the faucial tonsils. The face is lengthened ; the alæ nasi are collapsed ; the upper lip is short and retracted ; the mouth is often kept open, and a vacant expression is thus acquired : these constitute the *adenoid facies*. Pigeon-breast and a high palatal arch are often present also.

Symptoms. These, of course, vary with the amount of enlargement and consequent obstruction to the naso-laryngeal passage. They are deafness, habitual mouth-breathing worse at night, snoring and "night terrors," and liability to catarrhal rhinitis, with occasional blood in the secretion. In articulation the consonants M and N are badly pronounced, because these sounds cannot be resonated in the nasal meatus. Laryngismus stridulus, nocturnal enuresis, stammering, epilepsy and infantile convulsions are said by some to be excited by adenoids.

Treatment. If the symptoms are pronounced, the growths should be removed surgically. Slighter cases may be improved by breathing exercises, aiming at teaching the child to breathe through the nose.

LINGUAL TONSILS

The lingual tonsils are two or three nodules of lymphoid tissue, situate at the base of the tongue on either side of the middle line. They have the same structure as the faucial tonsil with two or three crypts. They may be inflamed like the faucial tonsils, less commonly have retention of secretion in the crypts, but occasionally hypertrophy, and this more frequently in children than in adults. It is probable that the sensation of "sore throat," which is felt in the middle line and somewhere at the back of the throat, is really in many cases due to inflamed lingual tonsils. The latter are also responsible for the common "tickling in the throat" that gives rise to a "throat" cough, and for the cough in whooping cough. Cough may be allayed by applying to the tonsils a saturated solution of 240 grains of ferric chloride made up to 1 oz. with glycerine, using a wool holder bent at the end. The tongue must be protruded as far as possible during the application (2).

CHRONIC PHARYNGITIS

Ætiology. Chronic inflammation of the pharynx may arise from repeated acute attacks. Infection passing down from the posterior nares is a frequent cause, and in all cases the condition of the nose and of the paranasal sinuses should be investigated. It also results from certain injurious influences, such as the abuse of alcohol, excessive smoking of tobacco, and the continual use of the voice; and when a public speaker inclines the head downwards in addressing an audience on a lower level, and consequently compresses the parts engaged in vocal utterance, he undoubtedly favours its occurrence. It is constantly associated with a similar change in the soft palate, tonsils, or posterior part of the nose.

Symptoms. The mucous membrane may be reddened, with dilated veins; in some cases there are numerous small grey elevations scattered over the pharynx (*granular pharyngitis*); in others small abrasions or ulcerations occur. The grey projections in *granular pharyngitis* are the enlarged follicles or mucous glands. In some cases the mucous membrane is covered with increased secretion, and the patient is constantly hawking and spitting; in others the surface is dry, and a certain amount of discomfort and difficulty in swallowing, with pricking pain and desire to cough, is the result.

Granular pharyngitis is often spoken of as a distinct affection. It may spread beyond the fauces proper to the top of the pharynx and to the larynx; the mucous membrane is in most cases dry, but sometimes the follicles are covered with viscid mucus. It may cause little or no discomfort; but there may be stiffness and dryness of the throat, constant desire to hawk and spit, and distress and difficulty in swallowing. The effort to talk is also painful, and the patient may be obliged to stop to clear the throat. This condition of things is not uncommon in clergymen, public speakers, and others of like vocation, and has consequently been called "clergymen's sore throat." The symptoms are aggravated by exposure to cold, and an inherited disposition has been observed by some writers.

Treatment. Local treatment is necessary in *granular pharyngitis*, and, more important, treatment of the paranasal sinus infection. Gargles are of little use, as they do not reach beyond the soft palate; but sprays of alum or tannin (4 to 10 grains of each to the ounce of water) may be employed, or the throat may be painted with astringent solutions, such as nitrate of silver (10 per cent. solution) or Mandl's pigment of iodised glycerine (iodine, 6 grains; pot. iod., 20 grains; ol. menth. pip., 5 min.; glycerine to an ounce).

RETROPHARYNGEAL ABSCESS

This, though chiefly a surgical complaint, requires short notice here, since it is apt to complicate the diagnosis of some throat complaints, especially laryngeal

obstruction. It arises from caries of the spine, but more often from inflammation of the retropharyngeal lymphoid tissue; and it forms a swelling at the back of the pharynx, which may press upon the larynx so as to cause dysphagia, dyspnoea, and asphyxia. Thus it may be mistaken for croup or laryngeal diphtheria, but the cough and voice are not husky and hoarse, as in the latter, but rather "gurgling." In a suspected case the finger should be passed to the back of the throat, when a fluctuating swelling will be felt. It should be opened by the surgeon.

LARYNGITIS

Laryngitis, or inflammation of the larynx, may be acute or chronic, and arises from a number of causes. Amongst these are—the ordinary conditions of catarrhal inflammation, considered under Acute Rhinitis; contact with irritating vapours and air charged with dust; the impaction of foreign bodies or direct injury in other ways; extension of inflammation from surrounding parts, the pharynx, the bronchi and trachea, or the tissues outside; acute specific fevers, such as those of diphtheria and measles; and finally Bright's disease. Chronic laryngitis is either due to infection from the upper respiratory tract or to infection from the lungs by tubercle; syphilis also attacks the larynx. The results differ somewhat according to the cause, and one can readily distinguish a catarrhal laryngitis, an oedematous laryngitis, the membranous laryngitis which is characteristic of diphtheria, and the laryngitis of phthisis and of syphilis.

Acute Catarrhal Laryngitis. This is mostly due to the same conditions as may cause an acute rhinitis, but it also arises from irritating vapours, dusty air, the entrance of foreign bodies, and inflammation spreading from the posterior nares, pharynx or bronchi. It occurs in measles, and less frequently in other infections.

Symptoms. The voice becomes hoarse or is entirely lost; there is a tickling sensation in the throat, leading to a husky cough, with expectoration from time to time of small plugs of mucus. Respiration is generally but little affected, but there may, in exceptional cases, be some stridor; and in children dyspnoea is much more often a marked symptom. Fever may be slight or none. On examination with the laryngoscope the mucous membrane over the arytenoids is swollen and red. The vocal cords are usually inflamed, but sometimes show little change: some mucus may be seen lying on and between them. The ventricular bands may be affected.

Children are liable to a form of acute laryngitis (*laryngitis stridulosa*), which is characterised by the sudden development of suffocative symptoms, frequently in the middle of the night. During the day there is only slight cough and huskiness, but some time in the night the child wakes up suddenly in terror, with severe dyspnoea and a barking or husky cough, followed by loud and prolonged crowing inspiration. The voice is husky and feeble and the features are congested; if the condition continues, the face may become pale and livid, and suffocation seems imminent. Usually, however, in a short time the symptoms become less severe and the child falls asleep. Either on the same night, after a few hours' sleep or on subsequent nights, the same attacks of threatening suffocation with croupy inspiration may take place. In association with these attacks there is more fever (white tongue, flushed face, hot skin, etc.) than commonly occurs in catarrhal laryngitis of adults. The attacks are probably due to laryngeal spasm set up by the presence of tenacious mucus in the glottis. The symptoms are apt to recur in the same child whenever it "catches cold"; they are, however, rarely fatal.

The **Prognosis** of acute laryngitis is mostly favourable; it generally subsides in the course of a few days.

The **Diagnosis** is generally simple, especially in adults: diphtheria is more severe, and may be accompanied by membrane on the fauces, by the expectoration of membrane, or by albuminuria.

Treatment. The patient must not speak. He should be placed in a uniformly warm atmosphere, and should inhale steam from a suitable apparatus frequently. This may be charged with tr. benzoin co. (℥ss to a pint of water). Sprays of menthol (gr. ii or iii in liquid paraffin ℥j), oil of eucalyptus, and creosote are also useful. Demulcent liquids should be drunk freely, or small pieces of ice may be sucked. The irritation of cough should be allayed by opiates. The diet or regimen usual in febrile affections will of course be followed.

For laryngitis stridulosa an emetic is often useful, such as sulphate of zinc (5 to 10 grains) or ipecacuanha (2 to 5 grains of powder, or a drachm of the wine every ten minutes, till vomiting is produced). In addition, hot flannels or a hot sponge should be applied to the throat. In the intervals the laryngitis is to be treated by a warm moist atmosphere (steam kettle) and small doses of bromides and chloral, internally.

Œdematous Laryngitis. This may be a result of laryngitis arising in various ways. It sometimes occurs in catarrhal cases, and in the course of Bright's disease. The usual cause is acute streptococcal infection of the larynx; it is accompanied by severe constitutional symptoms and requires early and vigorous treatment.

The localised œdema described as angeio-neurotic frequently occurs in the laryngeal tissues, and is often fatal (*see* Angeio-neurotic Œdema).

Morbid Anatomy. It consists of an effusion of inflammatory serum into the submucous tissue, and the serum contains many leucocytes, so that it may be sero-purulent, or actual pus is diffused through the tissue.

Symptoms often develop rapidly, a sore throat and some pain on swallowing are soon followed by dyspnoea, which may increase rapidly and demand tracheotomy. Laryngeal examination early reveals œdema of the epiglottis and arytenoids.

The **Prognosis** in cases of extensive œdema is a serious one.

Treatment. Early injections of anti-streptococcal serum are required. Inhalations as for acute laryngitis are comforting, as are cold applications to the neck. Low tracheotomy may become urgently necessary.

Membranous Laryngitis. The most common cause of membranous laryngitis is diphtheria, which either begins in the fauces and spreads to the larynx (*see* p. 65) or attacks the larynx at first, without either then, or later, involving the fauces. It is of interest to note that these primary laryngeal cases are more common in children than in adults, and that they are less often accompanied by albuminuria, or followed by paralysis, than those in which the throat first suffers.

A membranous laryngitis may certainly be produced by traumatic causes or local irritants, such as chemical vapours, boiling water, or impacted foreign bodies. A membranous laryngitis in measles means a superadded diphtheritic infection.

Symptoms. The local symptoms will be like those already described under Diphtheria, but the toxic symptoms of an infectious disease will be absent or little pronounced when the cause is traumatic.

Diagnosis. Generally speaking, children affected with dyspnoea, ringing or "croupy" cough, and inspiratory retraction of the chest wall, without apparent cause, and threatened with suffocation all within four days are suffering from membranous laryngitis; and in the majority of these cases diphtheria is the cause: but it is generally impossible to examine with the laryngoscope, and the first proof of the presence of membrane may be provided at or after the operation of tracheotomy. It is distinguished from laryngitis stridulosa (*see* p. 203) by the more gradual development and more uniform progress of the dyspnoea.

The alternative diagnosis is the presence of a foreign body.

Treatment. Membranous laryngitis may be treated as shown under Diphtheria both when it is due to this disease and when it is associated with

scarlet fever, measles, or other infectious illness. The antitoxin of diphtheria should be used in the first case.

Chronic Catarrhal Laryngitis. This often follows upon acute laryngitis, especially when the latter is not properly treated with complete rest of voice ; from infections in the upper respiratory tract ; from sinusitis or atrophic rhinitis or chronic nasal obstruction ; also from misuse of the voice.

The **Symptoms** are hoarseness and irritation of throat leading to dry cough. Laryngeal examination reveals thickenings on the true cords or in the posterior commissure.

Diagnosis is often difficult between chronic catarrhal laryngitis, tuberculous and syphilitic laryngitis and early neoplasm. For further information the student should apply to the special text-books on laryngology.

LARYNGEAL TUBERCULOSIS

Of patients suffering from phthisis, or pulmonary tuberculosis, a considerable number have a laryngeal affection, which was formerly described as laryngeal phthisis. This is due to the actual invasion of the laryngeal tissues by tubercle, and it is secondary to the formation of tubercle in the lungs. It is usually known as "laryngeal tuberculosis," and was present in 4·8 per cent. of phthisical patients admitted to King Edward VII.'s Sanatorium, Midhurst, in the first stage of the disease, in 18·3 per cent. in the second stage, and in 31·5 per cent. in the third stage. Men and women have an equal tendency to the disease (3). A second form of tubercle affecting the larynx is lupus, which spreads from the pharynx or nose.

Morbid Anatomy. The tubercles occur as minute collections of cells in the mucous or submucous tissues, forming, perhaps, slight prominences on the surface, leading in time to more or less, often considerable, œdema of the surrounding parts, and later to ulceration. In late cases the ulceration is widespread on arytenoids, ventricular bands, cords and epiglottis. Extending more deeply in severe cases, with the assistance of pyogenic organisms, the inflammatory process leads to deep ulceration, to perichondritis and to necrosis of the cartilages. The most frequent seats of the deposit are in the neighbourhood of the posterior commissure, *i.e.* the interarytenoid area, the anterior surface of the arytenoid body and the vocal processes. Next in frequency come the vocal cords.

The **Symptoms** are those of a chronic laryngitis, and in cases of ordinary severity consist of hoarseness of voice, frequent husky cough. Sometimes in early stages the voice may be lost entirely from functional failure. In later stages the voice is lost as a result of ulceration of the cords, and when ulceration attacks the posterior part of the arytenoids swallowing may be not only painful, but difficult on account of swelling of the tissues, or from their destruction preventing perfect closure of the larynx. The cough is occasionally severe and paroxysmal, and expectoration is variable, depending rather on the condition of the lungs than on that of the larynx. In a small number of cases, considerable obstruction to respiration arises. In 12 per cent. of cases the larynx was found to be tuberculous without producing any local symptoms at all.

In early stages the laryngoscope shows pallor of the mucous membrane, and a decided anæmia of the larynx occurs quite early in many cases of phthisis. Asymmetrical patches of congestion on the cords, ventricular bands and in the posterior commissure are characteristic of a mild degree : or in more severe cases a shallow ulcer may be seen on a ventricular band or on the epiglottis. When infiltration takes place the parts often assume a characteristic appearance, the ary-epiglottic folds on one or both sides being swollen up into a pale globular or pyriform tumour, the base backwards, the point forwards ; and when both are affected the swellings coalesce in the middle line. The epiglottis may form a

turban-shaped swelling; and the same thickening may effect the ventricular bands, which are, however, often concealed. Subsequently ulcers form upon the swollen tissues as well as upon the vocal cords, especially in the posterior halves.

Diagnosis. This must be made partly from the laryngoscopic appearances, and partly from the condition of the lungs, which are in many cases obviously tuberculous. The pyriform swellings of the ary-epiglottic fold are characteristic of the condition, but when they are absent there may be difficulty in distinguishing it from *chronic catarrhal laryngitis* and from *syphilitic* disease. In the former there are less swelling and more congestion than in tuberculous laryngitis; in syphilis the ulcers are generally larger and deeper, situated upon a more inflamed base, and solitary; the thickening is more irregular, and the disease often unilateral. The ulceration of carcinoma is sometimes difficult to distinguish from that of tubercle; carcinoma is always unilateral in early cases and occurs in older patients.

Prognosis. The presence of laryngeal tuberculosis makes the prognosis of the co-existing phthisis more gloomy (*see* p. 171). Recovery from laryngitis occurred in 25 per cent. of 477 cases at Midhurst. Very often the laryngeal condition progresses or retrogresses as the phthisis progresses or retrogresses; but this is not always the case. The larynx may recover, even though the phthisis gets worse; but with proper treatment the larynx never gets worse if the phthisis is improving.

Treatment. It is essential to treat the disease in the lungs of which the laryngeal tuberculosis is really a part. Intensive irradiation of the body with Finsen light is advocated as in Copenhagen. The most important element in local treatment of the larynx is complete silence on the part of the patient; not even whispering should be allowed. This may cause great mental strain in some patients. In such cases occasional whispering may be allowed. Where there is much infiltration galvano-caustic puncture with a fine platinum point introduced deeply into the tissue has been successful, but this should be employed only when there is no evidence of *active* disease in the lungs. Three or four punctures may be made at a time, after the production of anæsthesia by instillation of 5 drops of a 20 per cent. solution of cocaine. The puncture may be repeated at not less than two weeks' interval. For the pain in advanced cases insufflations of the larynx with orthoform and anæsthetics is helpful, and even an injection into the superior laryngeal nerves. In advanced cases tracheotomy may be considered in order to rest the larynx.

SYPHILIS OF THE LARYNX

Syphilis affects the larynx in many ways: in the hereditary form in infancy and childhood; in the acquired form in secondary and tertiary and intermediate stages. The secondary lesions of acquired syphilis are rare and consist of chronic hyperæmia, superficial ulcerations, and condylomas or mucous patches, of which the last are very rare. In the later stages of the disease a diffuse infiltration of the larynx is the most common. Small gummas varying in size from a pin's head to a pea and deep ulcerations are occasionally seen. Laryngeal œdema and perichondritis with laryngeal necrosis occasionally result, and the cicatrization of ulcers may lead to scarring, so that serious distortions of the larynx or contractions of the glottis ensue.

Symptoms. These are not distinctive, and vary much according to the severity of the lesion. They are hoarseness or loss of voice, occasionally cough in earlier stages, and more or less dyspnœa in later stages. Dysphagia is rare unless the epiglottis is the site of gummatous ulceration. Dyspnœa may come on rapidly and demand tracheotomy.

Diagnosis. Secondary laryngitis is diagnosed by the presence of other signs of syphilis, *e.g.* skin rash. Tertiary syphilis, apart from a typical gummatous

ulcer, may resemble tuberculous or chronic catarrhal laryngitis. A positive Wassermann test decides the diagnosis.

Treatment. Vigorous antisyphilitic treatment should be carried out. There is a belief, hardly justified, that potassium iodide may cause œdema of the glottis. Tracheotomy should be carried out in order to rest the larynx in the early stages and before cicatricial contraction makes it imperative. In the latter event a tube has to be worn for life; but attempts may be made to dilate the glottis mechanically, or to divide a web by the cutting forceps or dilator, or by the electric cautery.

TUMOURS OF THE LARYNX

Papilloma and *fibroma* are common on the vocal cords, all other benign tumours are rare. *Cysts* adjacent to the epiglottis often projecting into the vallecula are seen but are as a rule symptomless.

The **Symptoms** are hoarseness, and if papillomas are multiple or of large size, dyspnœa, which may be of such a degree as to demand tracheotomy.

The **Treatment** is removal by surgical operations, for the details of which the reader is referred to surgical works, or special treatises.

Malignant Tumours. These are mostly carcinoma, but sarcoma also occurs. They are more frequent in men than in women, and appear commonly after the age of 50. *Intrinsic carcinoma* of the larynx originates (1) on the vocal cords, more commonly on the anterior and central than the posterior regions; (2) in the subglottic region, more commonly in the anterior part of the larynx. A carcinoma of the cord may remain limited for a long time to the cord and the adjoining side of the larynx, but may spread eventually (a) across the anterior commissure; (b) to the subglottic region; (c) to the arytenoids. Eventually the whole larynx may be involved. In the later stages it ulcerates, vegetations spring up about the margins, and these ulcerate in their turn. The surface is often covered with pus, or sanguineous muco-pus, and occasionally free hæmorrhage takes place. Œdematous laryngitis and perichondritis occur as complications. The larynx is, of course, affected sometimes by carcinoma spreading from the pharynx (*extrinsic carcinoma* of the larynx).

Symptoms. The earliest symptom is huskiness or hoarseness of the voice. Laryngoscopic examination discloses a tumour. The cord is often freely movable during the earliest stages, but becomes fixed when the growth spreads. In the later stages there may be severe pain and dyspnœa. As ulceration proceeds the breath becomes fœtid, and hæmorrhage may occur. Gland involvement is very rare until a late stage of the disease.

The **Diagnosis** rests finally on biopsy.

The **Prognosis** is relatively favourable if the condition has been diagnosed in the earliest stage. From a series of fifty-one cases in which the growth was removed after laryngo-fissure there was no recurrence in 80 per cent. from one to thirteen years later, but a quarter of these had died from other causes. There was local recurrence in 16 per cent. The immediate operative mortality was very small (4).

The **Treatment** consists in removing the growth after laryngo-fissure; or by insertion of radium needles to the outer aspect of the growth through a window resection of the thyroid ala.

FOREIGN BODIES IN THE LARYNX

A large number of foreign bodies have at different times found their way into the larynx. Among these are peas, beans, buttons, coins, fragments of bone, shells, pebbles, artificial teeth, portions of solid food, and pieces of children's toys.

The **Symptoms** are divisible into three stages:—(1) The *initial spasm*, which takes the form of a violent fit of coughing, which usually dislodges the object. If this does not occur, the obstruction may be rapidly fatal; but if not, there

follows (2) the *quiescent period*, which may last any time from a few hours to many years. The symptoms may be so slight that it is not always known to the patient or to his friends that a foreign body has been introduced. (3) The stage of *inflammation*, due to infection, produces secondary symptoms, hoarseness, pain, coughing, etc.

At any stage a change in the position of the foreign body may cause sudden death.

Treatment. During stage (1) it may be useful to hold the head down, to help dislodge the body. If the symptoms appear dangerous, a tracheotomy should be performed. During stage (2) the body should be located and removed by means of an endoscope. If opaque to the X-rays, these may also be useful in locating the body.

PARALYSIS OF THE LARYNGEAL MUSCLES

From the peculiar course of the recurrent laryngeal nerve—the chief motor nerve of the larynx—paralysis of these muscles has often a diagnostic importance beyond that of the trouble arising locally. But it may be caused by lesions not only of the laryngeal nerves, but also of the vagus above their origin, and of the medulla oblongata where the nuclei are situated. Thus laryngeal paralysis is a part of bulbar paralysis, results from syphilis and tumours affecting the medulla oblongata and dura mater in the posterior fossa of the skull, and occurs occasionally in association with tabes dorsalis, general paralysis, syringomyelia, and disseminated sclerosis. The vagus in the neck may be compressed by tumours and enlarged glands, or may be injured by bullet wounds or cuts, whether accidental or in the course of surgical operation. The recurrent laryngeal nerves are in danger in two situations: the thorax and the neck; and the left is the more liable to lesion from its curving round the arch of the aorta, whereas the right goes no lower than the subclavian artery. Either of them may be involved in the fibrous thickening at the apex of the lung in chronic phthisis, but the left is especially liable to be compressed by aneurysm of the arch of the aorta, by mediastinal tumours, by enlarged bronchial glands, and by the dilated left auricle in mitral stenosis. In the neck the two nerves ascending to the larynx lie between the trachea and the œsophagus, and may be involved together in carcinoma of the latter, or compressed by an enlarged thyroid body. Paralysis also occurs as a result of diphtheria, influenza, polio-encephalitis and other infectious diseases, chronic alcoholism, and poisoning by lead and arsenic.

In all these cases the paralysis affects the abductor muscles of the vocal cords in the first place, and only later are the adductor muscles involved. When the adductor muscles only fail to act the affection is functional or hysterical (see later).

Complete Paralysis of the Vocal Cords. When all the muscles moving the vocal cord are paralysed the cord takes up a position between *adduction* and *abduction* which is known as the *cadaveric* position.

The voice is then weak and may become higher in pitch when an attempt is made to speak loudly. It may be reduced to a whisper, coughing is impossible, during sleep there is noisy stridor, and indeed the danger of suffocation on account of sucking together of the flabby cords calls for tracheotomy. This condition is seen typically in tabes dorsalis.

Paralysis of the Abductors. Although the recurrent laryngeal nerves, supplying as they do all the muscles of the larynx except the crico-thyroid, must contain fibres for both *adductors* and *abductors*, it is a remarkable fact that coarse progressive lesions of these nerves (compression by tumours or aneurysms) result at first in paralysis of the *abductors* (*crico-arytænoidei posteriores*) alone; it is only later that the internal tensors (*thyro-arytænoidei*) are affected, and last of all the chief adductors (*crico-arytænoidei laterales*). The abductor fibres form

a separate bundle lying internal to the adductor fibres in the recurrent laryngeal nerve of the dog (Risien Russell); but their greater liability to suffer from lesions affecting the whole nerve is apparently due, as shown experimentally, to less powers of resistance to external influences. Abductor paralysis also results from lesions of the medulla where it may be supposed it sometimes depends on a separate affection of the nucleus of the abductor fibres, though adductor paralysis alone never arises under such circumstances. Syphilis and tabes are the most common associates of abductor paralysis arising in this way. It is to be noted that there are no supranuclear lesions of the abductors. Abductor paralysis is probably sometimes the result of a change primarily in the muscle.

The effect of the lesion is that the cord during respiration, not being fully abducted, remains in the cadaveric position, and at first allows ample space for the passage of air; after a time, however, the antagonistic muscle, or adductor, contracts, and the cord is drawn into a position of adduction. Thus in bilateral paralysis of the abductors the cords are seen to be permanently approximated in the middle line to within one-tenth of an inch of each other; on attempted phonation they meet completely in the middle line; on inspiration they do not separate, but are even drawn a little closer together; on expiration they scarcely move, or only in the reverse sense to their slight movement in inspiration. The important symptom is *dyspnœa*, which results from the permanent narrowing of the glottis; this is generally accompanied by *stridor* on inspiration, which is worse on exertion, and often extremely loud during sleep. The voice is clear, or it may be a little hoarse. Coughing can be perfectly effected.

When only one cord is paralysed, *dyspnœa* only occurs on exertion, and the *stridor* is absent. On phonation the healthy cord meets the paralysed cord beyond the middle line, and the patient can speak.

Diagnosis. Abductor paralysis may be confounded with spasm of the adductors, with ankylosis of the arytenoids in the position of adduction, and with perverted action of the cords in which they move inwards instead of outwards during inspiration. When the arytenoid is ankylosed the cord is absolutely fixed, and there is generally some thickening about the joint.

It is important to remember that the lesion which causes unilateral or bilateral abductor paralysis may at the same time cause narrowing of the trachea by pressure (aneurysm, tumour) or by cicatrix (syphilis), and the *dyspnœa* and *stridor* due to the latter may be wrongly attributed to the former. Tracheal stenosis usually causes expiratory as well as inspiratory *stridor*; nevertheless the certain recognition of a tracheal obstruction in the presence of laryngeal stenosis is by no means easy (*see also* p. 129). The diagnosis of the remote cause of the paralysis has next to be made by a consideration of other symptoms, such as those in favour of tabes and central nervous lesions, or of thoracic aneurysm and new growths in the neck or chest. Aneurysm is a very frequent cause of paralysis of the left vocal cord. Wassermann's test and the Röntgen rays may have to be used.

The **Prognosis** is generally serious. Except when syphilis is the cause, there is little hope of recovery; when there is double abductor paralysis a constant liability to death from suffocation is present. If the adductors are subsequently paralysed, the obstruction to breathing is diminished, but aphonia ensues. Death may arise from the primary lesion, such as œsophageal cancer or double aneurysm. In long-standing cases the posterior crico-arytenoid muscles become completely atrophied.

Treatment. If the cause of double paralysis is central, or if syphilis is the cause, a vigorous antisymphilitic treatment should be instituted. But if no improvement takes place in a few weeks, and if *dyspnœa* is constant, or night attacks take place, tracheotomy should be performed and the tube should be worn constantly.

In unilateral paralysis the risk of asphyxia is much less, and the treatment may be directed mainly to the cause.

Paralysis of the Adductors. This is a functional disorder, and rarely occurs alone from structural lesions. The adductors are the lateral adductors, or *crico-arytænoidei laterales*, and the central adductor, or *arytænoideus proprius*; the inner fibres of the *thyro-arytænoidei*, or internal tensors, also act as adductors of the anterior portions of the vocal cords. In the most common form of adductor paralysis these are all affected. When examined with the laryngoscope, the glottis is seen to be widely open; on attempts to speak the cords scarcely move, but remain still at the sides of the larynx. As the cords cannot be approximated, the patient speaks only in a whisper, no laryngeal voice being produced, though sometimes, with an effort, a momentary contact of the cords may be effected. Coughing, in which the cords are brought together by involuntary reflex action, is generally perfect; and from the open condition of the glottis there is no dyspnoea. This constitutes *functional* or *hysterical aphonia*, which is, however, often started by slight catarrh of the larynx, *e.g.* in the earliest stage of phthisis, or by sore throat, or by other local trouble, both in definitely hysterical persons and in others suffering from anæmia or general weakness. In civil practice it occurs in young women and boys as the result of an emotional shock, the individual being struck dumb with terror. The same explanation must be given for most of the numerous cases of aphonia in soldiers invalided from the War, especially when they were exposed to shell fire, or buried after explosions, or otherwise directly injured. Some of the cases, in which a child fails to speak after the removal of a tracheotomy tube worn for some weeks, are also due to functional adductor paresis.

Sometimes the adductor paralysis is less extensive; the internal tensors may be alone affected, so as to produce want of contact of the cords on attempted phonation, each cord presenting in its anterior half a concave margin towards the middle line. And sometimes the central adductor is paralysed, in which case the anterior portions of the cords come into contact, and a triangular space is left open behind, between the arytenoid cartilages. These last two forms are not uncommon in the course of catarrhal laryngitis. They may occur together, producing defective closure in front and behind, while the *processus vocales* are in contact. In these cases the loss of voice is not so complete as in that first described.

The **Diagnosis** of these conditions is easily made with the laryngoscope. Even without this, the voicelessness of the patient, the absence of dyspnoea, cough, and expectoration, and the power to cough at will, are sufficiently distinctive. Should there be, however, any visible evidence of catarrh, or recurring attacks of aphonia, the possibility of a tuberculous lesion underlying it should not be forgotten.

The **Prognosis** is favourable, and cases of many years' duration may be at length cured.

Treatment. Functional aphonia is to be considered as a symptom of hysteria, and to be treated as such. In most cases it may be removed by means of the methods of suggestion and re-education. In some instances it is sufficient after a preliminary explanation of the fact that the weakness is not due to any organic disease, but is rather of the nature of a forgotten habit, to induce the patient to cough, and to prolong the noise in the form of an "a-a-h." From this he is led on to the letter "A," and so through the alphabet, beginning with the vowels, when it may be demonstrated to his own satisfaction that he can now phonate properly in the formation of words and sentences. This method must not be used if there is any suspicion of tuberculosis. In other cases the application of a faradic current externally in the neighbourhood of the larynx or to the back of the throat may be useful as a method of crude suggestive treatment. If the symptom is not amenable to such methods or recurs, or if it is associated

with other evidences of hysteria, further treatment should be undertaken on the lines recommended under that heading (*see* p. 791).

SPASM OF THE GLOTTIS

In this affection the adductors are spasmodically contracted, and complete closure of the glottis takes place, preventing the entrance of air, and producing asphyxia, or even death. It may occur at all ages, but is especially frequent in infants, in the form now to be described.

Laryngismus Stridulus (*Spasmodic Croup, Child-crowing*) This occurs between the ages of three months and two years, and is more common in boys than in girls. It is promoted by imperfect hygienic conditions, and is more frequent among the poor, and in children who are hand-fed, or nursed by sickly and half-starved mothers. In the majority of cases (75 per cent.) there is evidence of rickets, and the disease often occurs in children who have symptoms of tetany. Laryngismus stridulus is also apt to follow whooping cough. Attacks occur by night and day; but a number of causes may excite a spasm, such as crying, sucking, quick movements, milk getting down the larynx, indigestible food in the stomach, the irritation of dentition, and fits of anger; but the attacks often occur without any such obvious antecedent. The child may be in fairly good health when it is noticed to make a slight crowing sound occasionally. This may be repeated at intervals without giving rise to any alarm, but it gradually becomes more frequent. After a while the interruption to respiration, at first only indicated by the crowing, becomes more marked. Breathing ceases, the chest is fixed, the face becomes pale and livid, the head is thrown back, and the facial muscles are slightly twitched. In a short time the spasm yields, and the air enters with a loud crowing noise through the still imperfectly opened glottis; and the child in a few minutes more may return to its playthings. In the severest cases the glottic spasm is accompanied by the *carpopedal contractions* of tetany; the fingers are bent into the hand, the thumb within the fingers, and the hand is flexed on the wrist; the legs are extended, the feet bent on the legs, the soles turned inwards, and the great toe widely separated from the others. General convulsions may be added to these. Occasionally death takes place during a fit, from complete stoppage of the respiration; and as the crowing is really the signal that the spasm is relaxing, it will be seen that in the fatal cases death may occur quite silently.

Diagnosis. The symptoms are very characteristic, and not easily confounded with those of any other disease. The absence of fever, the shortness of the attack, and the completely healthy condition between the attacks, distinguish it from laryngitis. It may be simulated by the presence of a foreign body (*see* p. 207).

Prognosis. Most patients recover completely, but occasionally deaths are reported.

Treatment. This has to be considered in relation to the general health of the patient, and the occurrence of the attacks. The child must be put immediately under the best possible hygienic conditions: fresh air, well-ventilated rooms, and improvements in its food where this is insufficient or unsuitable (*see* Rickets), and attention to the bowels should be secured. Medicinally cod-liver oil, or cod-liver oil with malt extract, is of great value, and potassium bromide may be given three times daily, in doses of 2 to 5 grains, according to the age of the child, and small doses of chloral. If the attacks are slight, sponging the child from head to feet two or three times daily with cold or tepid water, according to the season, often quickly stops them. In the more severe fits, the head should be raised, the surface of the body and face slapped with a towel dipped in cold water, and ammonia or acetic acid held to the nostrils, or the body may be immersed in warm water, and cold water poured over the head and face. The finger should be inserted and the epiglottis pulled forward.

Spasm of the Glottis in Adults. This occurs more frequently in connection with laryngitis, œdema of the larynx, paralytic conditions, or the presence of foreign bodies ; it may also be a danger in epilepsy, chorea, tetanus, hydrophobia, and tabes dorsalis. In the last it constitutes the severer form of laryngeal crisis (*see* p. 679) ; and this may occur in the healthy larynx, or in one already affected by a paralysis, which is generally of the abductor variety. The entrance of saliva or small particles of food or drink into the larynx may cause most dangerous spasm, and a certain amount is often induced by the application of medicated solutions to the mucous membrane of the larynx. Spasm of the glottis is often the result of hysteria. Allied to this is a functional spasm (*phonic spasm* or *mogiphonia*), brought on in some neurotic persons by the effort of speaking, and relaxing when the attempt to speak is abandoned ; it may be confined only to the use of the voice in public, as in singers and teachers.

Treatment. In the first class of cases inhalation of chloroform, amyl nitrite, vapor coninæ, or burning stramonium should be employed, if they can be obtained in time ; otherwise tracheotomy may be necessary. The bromides may be given for recurrent attacks.

Hysterical cases require the general treatment of hysteria ; and the other functional conditions must also be treated with reference to the general condition of the patient, as well as by breathing exercises, and exercises in voice production.

CONGENITAL LARYNGEAL STRIDOR

Infants are occasionally the subjects of a laryngeal disorder, in which the breathing is accompanied by a peculiar croaking sound. This is generally first heard soon after birth, is continuous for long periods, perhaps all day and night, but may be absent for a few hours at a time. The croaking takes place with inspiration, and is either a rough sound, or more clear and musical ; expiration is silent ; the cough and cry are, as a rule, normal. There may be a little sucking in of intercostal spaces, but there is rarely any lividity. In some cases the noise is constant during sleep ; in others it is absent. It is generally worse when the child is lively or excited. It subsides as the child grows older, but Sir Frederick Taylor found it still present at two and a half years. The child appears to be in other respects quite healthy.

Both during life and after death the glottic aperture is seen to be extremely narrow, the epiglottis being folded on itself, and the ary-epiglottic folds almost in contact. This, however, is only an exaggeration of the normal condition of the infant's larynx, and Dr. Paterson has shown, by direct observation in five cases, that the stridor was due to the drawing into the larynx at each inspiration, and the vibration in this position, of the arytenoids and lax mucous membrane on the upper edge of the cricoid.

The obstruction caused by the deformity diminishes as the parts develop. No direct treatment is of any avail. Tracheotomy might be necessary in the rare event of life being threatened by asphyxia.

ANÆSTHESIA OF THE LARYNX

This occurs in diphtheria, in bulbar paralysis, in tabes dorsalis and general paralysis, and from injury to the vagus or superior laryngeal nerve. It is recognised by the insensibility of the laryngeal mucous membrane when touched with a probe, introduced with the help of the laryngoscope. It is often accompanied by dysphagia from particles of food entering the larynx, the result, according to M. Mackenzie, of paralysis of muscles supplied by the superior laryngeal nerve, *i.e.* those which depress the epiglottis and close the upper aperture of the glottis during swallowing. Anæsthesia from diphtheria usually recovers ; the prognosis is generally bad in progressive bulbar paralysis and allied conditions, as food is apt to get into the lungs and set up pneumonia.

The Treatment should be by means of galvanic and faradic applications. Strychnine may be given internally, and dysphagia may necessitate feeding with the œsophageal tube.

THE EAR

The ear consists essentially of three parts :

- (1) The conducting apparatus by which sounds are conveyed to
- (2) The perceptive apparatus or cochlea, which lies in the dense bone of the internal ear ; from this
- (3) The auditory nerve (cochlear division) carries the impulses to the brain.

The conducting apparatus includes the pinna, the external auditory meatus, the tympanic membrane which is the outer wall of the middle ear, containing the ossicles, malleus, incus and stapes : this last fits by a water-tight joint into the oval window, and this is one of the two bony openings into the internal ear ; the other opening is the round window which is closed by a membrane. The internal ear is filled with fluid. Opening into the middle ear is the Eustachian tube from the naso-pharynx ; on swallowing this tube is momentarily opened so that pressure in the middle ear is kept equal to that outside ; the movable tympanic membrane thus maintains its normal position. Auditory impulses as sound waves enter the external auditory meatus and arrive at the tympanic membrane. The vibrations of the membrane in turn are transmitted to the malleus, incus and stapes and thus arrive at the oval window ; an alternative wave can arrive at the round window through the air of the tympanum. These waves are then transmitted through the fluid of the internal ear to the very specialised organ of Corti in the cochlea ; the impulses are thence passed *viâ* the spiral ganglion to the cochlea nerve and so to the brain. Any interference with this mechanism produces deafness.

Deafness. Three classes of deafness are distinguished :

(A) Conduction Deafness ; this includes all causes up to the oval and round windows. Examples are : *wax* or foreign bodies lodged in the meatus ; all forms of middle ear catarrh ; acute and chronic inflammations of the middle ear.

(B) Perception Deafness ; those causes that involve the cochlea, spiral ganglion and auditory nerve ; it is also called Internal Ear Deafness. It may result from senile causes, syphilis, scarlet fever and typhoid ; from certain trades, *e.g.* boiler-makers and caisson workers, from exposure to the firing of revolvers, rifles and guns ; from taking of certain drugs, notably quinine and salicylates and excessive smoking.

(C) Nerve Deafness ; lesions of the auditory nerve itself and of its central nervous connections. This is always complete deafness ; it may be (1) *unilateral* : from mumps, acute labyrinthitis, the involvement of the auditory nerve in tumours ; (2) *bilateral* : from cerebrospinal meningitis, congenital syphilis—in this case it is almost always accompanied by interstitial keratitis and bilateral acoustic nerve tumours.

For tinnitus and vertigo and Ménière's disease, see Diseases of the Nervous Systems.

Earache. Pain in or about the ear is due to local inflammation in about 95 per cent. of cases ; in the remaining 5 per cent. of cases, no local cause is found and the pain is a referred one ; these are spoken of as cases of *otalgia*.

Examination of the pinna, external meatus and tympanic membrane will reveal a local cause, generally inflammatory, erysipelas, boils in the meatus or a red and bulging tympanic membrane and appropriate treatment will relieve the pain. Occasionally ulcerations in the meatus or carcinoma of the middle ear occur. When no local cause is found a wide search is needed to find the source of *otalgia*.

Pain may be referred to the ear from other parts supplied by the same nerves as also supply the ear. (1) Trigeminal ; this may be a true neuralgia. *Otalgia*

is also frequently referred from carious lower teeth and from unerupted wisdom teeth almost invariably in the lower jaw ; from disease of the tongue, growths and ulcerations ; from inflammations of the parotid gland and arthritis of the temporo-mandibular joint. (2) Glosso-pharyngeal ; this may be a true neuralgia, but pain is also referred from inflammatory or ulcerative lesions of the Eustachian tube and naso-pharynx (carcinoma) of the tonsil, epiglottis, back of the tongue, ary-epiglottic fold and pyriform fossa ; pain in the ear may be the first symptom of carcinoma of the pyriform fossa. (3) Spinal cervical 2nd and 3rd nerves inflammation of the posterior roots with herpes on the scalp and pinna is a source of severe otalgia, as also are lesions involving the cervical plexus. (4) Auricular branch of the vagus, which is doubtless intimately connected with the geniculate ganglion of the facial nerve. Inflammation of this ganglion occurs with a resulting herpes over the area supplied by this auricular branch ; this may be accompanied by facial paralysis and deafness and vertigo.

SUB-ACUTE OTITIS MEDIA

This denotes a mild infection of the middle ear, accompanied by catarrh of the Eustachian tube. The latter tends to be blocked so that the air becomes absorbed and there may be serous exudation, with drawing inwards of the tympanic membrane.

Symptoms. There is discomfort, or slight pain in the ear, deafness, which is apt to be overlooked in children. The patient hears the middle tones of the tuning-fork ; but loses perception of the lowest and highest notes. **Treatment** consists in removing septic foci if present in the nasal sinuses and naso-pharynx, and dealing with the Eustachian obstruction and sometimes removing fluid.

ACUTE SUPPURATIVE OTITIS MEDIA

Ætiology. This infection of the middle ear is nearly always due to a streptococcus, and very often follows the common cold, tonsillitis, scarlet fever, measles, influenza, or is part of a septicæmia. The whole of the middle ear tract may be involved. There is hyperæmia followed by exudation into the tympanum of blood-stained serum which usually becomes purulent in forty-eight hours.

Symptoms. Earache is usually the first symptom, but in children it may be so slight as to be overlooked, while in adults there may be severe headache. There is always deafness and frequently tinnitus. There is the malaise that accompanies any fever ; vertigo is infrequent. Infants may roll their heads from side to side and may develop meningismus. On examining the ear there is at first redness in a line behind the handle of the malleus ; then radiating vessels are seen running from this point to the periphery of the membrane ; later the redness is diffused, but the posterior half of the membrane is always affected first and more markedly than the anterior half. Inflammatory exudation causes bulging of the membrane which may lead to a perforation in the posterior half.

Complications. In some cases recovery takes place with perforation of the membrane, or occasionally without. Incomplete recovery leads to : (a) Deafness, which may later be improved by inflating the middle ear through the Eustachian tube. (b) Continued discharge ; this is sometimes associated with granulation (polypus) which projects into the perforation and prevents drainage. If the discharge persists for five or six weeks the mastoid will probably be infected ; but before a mastoid operation is performed infected foci in the nose or naso-pharynx must be excluded ; removal of adenoids may bring the suppuration to an end. (c) Facial paralysis from pressure on the seventh nerve, through a congenital aperture in the Fallopian canal. (d) Paralysis of the sixth cranial nerve which may be accompanied by pain in the frontal and temporal regions and is perhaps the result of a serous meningitis. (e) Mastoiditis, which is recognised

by pain behind the ear, tenderness on pressure over the mastoid—especially its tip—and swelling of the soft tissues over the bone. Bulging of the deepest part of the external auditory meatus is a valuable sign. In advanced cases there is much swelling over the mastoid process and above the ear with redness of the skin. Mastoiditis may lead to (*f*) abscess on the lateral sinus dura which may compress the sinus and later cause thrombosis, (*g*) extradural abscess in the middle fossa which is rare, (*h*) cerebral abscess which has been known to occur without pus formation in the mastoid, (*i*) suppurative meningitis.

Treatment. The patient will be kept in bed ; drugs are given to relieve the pain such as acetyl salicylic acid, pulv. ipecac. co., and morphia if necessary. Injections of anti-streptococcal (anti-scarlatinal) serum may be given in doses of 12 c.c. on two or three succeeding days intravenously or intramuscularly. Drops of glycerine and carbolic or 4 per cent. cocaine in camphor water are instilled into the ear ; warmth by means of an electrically heated pad or wool or hot-water bottle or fomentations over the ear may be used. Alternatively small ice bags kept permanently over the mastoid relieve the pain and inflammation. It may be advisable to incise the tympanic membrane, especially in acute cases, with much pain or high temperature. Treatment of mastoiditis is outside the scope of this book.

DISEASES OF THE ORGANS OF CIRCULATION

IN the working of the normal heart, two kinds of structures are concerned: the muscular contractile walls of its cavities, which drive the blood, and the valves, which control the direction of its flow. The power of rhythmical contraction is inherent in the heart muscle. The researches of the last few years have shown us the points in the myocardium at which stimuli to contraction commonly arise, the paths of conduction of stimuli from auricle to ventricle, the normal rate of such conduction, and the fact that contraction, though usually initiated in the auricle, and passing to the ventricle, may, in certain circumstances be started in the ventricle. After each ventricular systole there is a period of rest from contraction, which is broken by the systole of the auricle, and this is immediately followed by the systole of the ventricle. Three structures are involved in this process: one a small elongated mass of nerve tissue and muscular fibre and cells situated near the attachment of the superior vena cava to the auricle, called the *sino-auricular node*; another, a small mass situated in the septum of the auricles, near the opening of the coronary sinus, called the *auriculo-ventricular node*; the third, a special band of muscular fibres known as the *auriculo-ventricular bundle*. This band arises in the auriculo-ventricular node and measures about 2.5 mm. in breadth: it passes from the auricular septum into the ventricular septum, lying at first below the *pars membranacea septi*, and there divides into two portions, which lie one on each side of the septum ventriculorum; the right branch passes into the moderator band. Each branch is distributed extensively in the wall of its own ventricle, terminating in Purkinje's fibres, which lie beneath the endocardium in nearly all parts of the ventricles. The auriculo-ventricular node and the auriculo-ventricular bundle are sometimes called *junctional tissues*. In the normal action of the heart, the stimulus starts in the sino-auricular node, and is transmitted to the auricles. The wave of contraction which is slightly preceded by an electrical wave, called the excitation wave, spreads out radially from the S.A. node, travelling with equal velocity in all directions. The A.V. node then becomes stimulated. The excitation from the A.V. node spreads down the A.V. bundle along its various ramifications, and is spread out in the Purkinje network over the endocardium of the ventricles, and from here it spreads at right angles into the muscle of the ventricle.

The heart muscle is supplied by two sets of nerve fibres: (1) from the vagus; (2) from the sympathetic. Their function is to modify the beat. Very little is known about the sympathetic apart from the fact that its stimulation accelerates the heart and strengthens the beat. Branches from the vagus end both in the S.A. and A.V. nodes. Stimulation causes the seat of origin of the excitation wave (pacemaker) to move from the upper to the lower end of the S.A. node. Other effects are described under Bradycardia.

EXAMINATION OF THE HEART

Like the lungs, the heart is accessible to examination by the eye, the hand, and the ear. It comes into close proximity with the chest wall between the anterior margins of the lungs, over an area corresponding to the lower half of the sternum

on the left of the middle line, and the inner portions of the fourth and fifth left costal cartilages and the spaces below them. The *impulse* of the heart can be determined by inspection and palpation; the *præcordial area*, or the area of chest wall over the heart, can be made out by percussion, and the *heart sounds* can be studied by auscultation.

INSPECTION

In healthy persons, not very fat, the heart can be seen to beat over an area of about $\frac{1}{2}$ inch in diameter in the fifth intercostal space, from $\frac{1}{2}$ inch to 1 inch within a line drawn vertically down from the nipple, or from $2\frac{1}{2}$ to 3 inches from the middle line in an average-sized adult; this beat is called the *impulse*, or *apex beat*. In disease sometimes no impulse can be seen, either from feebleness of beat, or because the heart is overlaid by lung. The right auricle, when dilated, can sometimes be seen beating to the right of the sternum. Inspection also shows bulging of the chest wall in some cases of great enlargement of the heart.

A slight visible *systolic retraction* of intercostal spaces is not uncommon in healthy persons; a more marked retraction occurs with hypertrophy of the heart.

PALPATION

The position of the impulse can usually be more closely defined by palpation than by inspection. In hypertrophy of the left ventricle it may be displaced outwards and downwards; in extreme dilatation it may be felt in the axilla. The beat may be forcible or heaving and quick and irregular. It may not be palpable at all. Examination by X-rays shows that the left border of the heart usually corresponds with the point furthest to left, where a definite forward and horizontal lift is imparted to the fingers (63), and not with the outer and lower part of the area over which the vibrations can be felt, which is commonly outside the area of the heart, as shown by X-rays. In one case observed by the writer an apparent impulse was produced in the fourth space by the upper part of the left ventricle. A *systolic* impulse may be produced in the epigastrium by a hypertrophied right ventricle, by the aorta, whether aneurysmal or conducted by tumour, or by a pulsating liver. A dilated right auricle may be felt beating to the right of the sternum. In some cases of aortic aneurysm the hand placed over the base of the heart can appreciate a shock described as the *diastolic shock*, or *diastolic rebound*, which can be readily felt because the aneurysm compresses the lung and comes into closer contact with the thoracic parietes.

In some cases of valvular disease, over a limited area in which a murmur can be heard with the stethoscope, a *thrill* (*frémissement cataire*) can be felt by the hand. It is usually accompanied by a murmur, but occasionally the murmur is absent, because the vibrations are so coarse (*i.e.* their rate is so slow) that they can only be felt, not heard. It is most common in mitral stenosis, and accompanies a large proportion of auriculo-systolic murmurs, and some mid-diastolic murmurs. Thrills with other murmurs are much less common and occur in other valvular lesions, such as pulmonary stenosis (congenital), aortic stenosis, and occasionally aortic regurgitation and mitral regurgitation. Aneurysms and pericarditis may also give rise to palpable vibrations.

PERCUSSION

While the greater part of the chest is resonant to percussion, from the presence of the lung, there is a small area of *superficial* or *absolute dulness*, which corresponds to that part of the anterior surface of the heart which is not covered by lung. Around this dulness is an area of *deep* or *relative dulness*, the outer limit of which corresponds to the outline of the heart, and therefore maps out its actual size. Above it reaches to the third space; to the left it reaches to the

impulse ; and to the right it can often be made out half an inch beyond the right border of the sternum. The sternum itself is resonant. The relative dulness is best obtained by means of moderately light percussion. The room must be quiet. X-ray examination shows that the border of the heart usually corresponds to the point where the note first undergoes a considerable change in resonance. The lower limit of the heart's dulness cannot be discriminated from that of the liver, and the outline is assumed to lie between the impulse and the lowest point of the right border of the dulness.

The position of the heart varies slightly with the position of the patient. The area of its projection on the chest wall extends rather lower, but it is less wide in the vertical than in the horizontal position.

When the lungs are distended, as in emphysema, it is usually quite impossible to tell the size of the heart by percussion, and in addition the impulse is often too weak to feel. An important cause of the enlargement of the area of relative dulness is distension of the pericardial sac with liquid. Exceptionally, the area may be resonant from the presence of air in this sac. The area of præcordial dulness is shifted upwards, downwards, or to either side by anything which displaces the heart in these directions.

AUSCULTATION

Heard with the stethoscope the sounds of the heart resemble the syllables "lubb dup" ; the *first* sound duller and longer, and the *second* sound sharper and shorter. The first sound is due partly to muscular contraction, and partly to sudden stretching of the auriculo-ventricular valves after closure ; the second is due to sudden stretching of the semi-lunar valves after they close. In the case of both valves, the flaps normally float together immediately after the blood has stopped streaming through the orifice (1). The first sound is heard best near the apex of the heart, and the second is heard best at the base.

Modifications of the Sounds. The heart sounds may be accentuated or diminished in loudness, or increased in number, or their time relations may be altered.

Accentuation arises from several causes, amongst others from retraction of the lung, so as to bring the heart closer to the chest wall. Accentuation and dulling or muffling of the first sound results from ventricular hypertrophy, while accentuation without dulling is common in mitral stenosis. Accentuation of the second sound in the second *right* intercostal space results from increased arterial blood pressure, whereby the valves are stretched with unusual force after closure (Plate 10, B (2)) ; and accentuation of the second sound in the second or third *left* space results similarly from the pulmonary valves.

Diminution of the sounds results from feeble action of the heart, from its being unusually covered by lung, as in emphysema, or from its being surrounded by pericardial effusion. The heart sounds may also be diminished if the valves are imperfect so as to allow regurgitation of blood with production of *murmurs*.

Reduplication of the *second* sound is commonly heard at the base of the heart, especially in the pulmonary area, and it is occasionally conducted to the apex. It occurs in cases of valvular disease where there is congestion of the lungs and increased pressure in the pulmonary circuit. It is due to the fact that the pulmonary and aortic valves do not close quite synchronously. It is probable that reduplication of the *first* sound, heard at the apex, may sometimes be due to asynchronous closure of the A.V. valves. In *canter-rhythm* there is very well marked reduplication of the first or second sound at the apex, so that there is a triple rhythm of two types, "te-lubb dup" and "lubb dup-te." There are two causes for canter-rhythm : (1) The extra sound is due to the same cause as often produces an early mid-diastolic or an auriculo-systolic murmur in this position ; *i.e.* it is an indication of mitral stenosis ; (2) it is due to heart block (*q.v.*), and may

short, or it may be rumbling and continue through most of diastole, and this suggests a high degree of stenosis. The auriculo-systolic murmur gets gradually louder, and ends in an accentuated first sound. It may be represented by "r-r-rup." It is possible to have both mid-diastolic and auriculo-systolic murmurs present at the same time (C and D), or an auriculo-systolic murmur may be accompanied by a reduplicated second sound.

What is here stated of the aortic and mitral valves may be said, *mutatis mutandis*, of the pulmonary and tricuspid valves.

The relation of the murmurs to the rhythm of the heart and the flow of blood through it may be tabulated as follows :

Orifice.	Lesion.	Murmur.
Aortic or Pulmonary.	{ Obstruction.	Systolic.
	{ Regurgitation.	Diastolic.
Mitral or Tricuspid.	{ Obstruction.	Diastolic
	{ Regurgitation.	Systolic.
		{ Early. Mid. Late (Pre-systolic or auriculo-systolic)

Of these the pulmonary regurgitant and tricuspid obstructive murmurs are very rare ; and murmurs due to pulmonary obstruction are less frequent than the remaining five, although a systolic murmur over the region of the pulmonary artery is quite common in association with changes in the quality or quantity of the blood, and is known as a hæmic murmur.

Obviously, the eight possible lesions above indicated (obstruction and regurgitation at each of the four orifices) cannot be distinguished solely by the relation of their murmurs to the sounds of the heart. But we find help towards their discrimination in the different points of the præcordial area at which they are best heard. These are determined not by the actual position of the valve below the surface, but by the direction of the current of blood which is flowing past the orifice, and in which the sound vibrations are produced. The flow of blood in the aorta from mid-sternum towards the right clavicle, in the pulmonary artery from the sternum upwards towards the left, and in the heart from auricle to ventricle, conveys each murmur along a special path ; and the reflux of blood through the aortic valves into the ventricle, and through the mitral valves into the auricle, acts in a similar way in the case of regurgitant murmurs. The term *area* (mitral area, aortic area) is often applied to the part of the præcordia or adjacent chest wall where a particular murmur is commonly heard, and in auscultating the heart for valvular disease these areas must be successively examined.

Aortic obstructive murmurs are heard with greatest intensity at the junction of the second right costal cartilage with the sternum, and at the extremity of the second right intercostal space (aortic area) ; they can be traced upwards towards the inner half of the right clavicle, and into the vessels of the neck, and they are sometimes heard in the right supraspinous fossa.

Aortic regurgitant murmurs are heard over the aortic area ; they are traceable down the sternum or along the left-hand side of it, towards the apex of the heart, i.e. along the line of the regurgitating stream of blood. They are usually loudest to the left of the sternum, and sometimes this is the only place where they can be heard.

Mitral obstructive murmurs are heard most loudly at the point of impulse of the heart against the chest (mitral area) ; though sometimes audible more or less imperfectly between this point and the sternum, they are always best heard at the apex, and are often strictly limited to an area of an inch or an inch and a half in diameter. The stethoscope should always be placed over the actual heart beat, as found by examination, and not only over the spot where the impulse should be normally found. They are heard best if only very light pressure is used.

Mitral regurgitant murmurs are mostly heard with greatest intensity at the

apex of the heart, but they are commonly widely diffused over the præcordia towards the sternum and the base of the heart, though as a rule they are heard more loudly when traced outwards to the left. In the axilla they often lose in loudness, but they are again heard at the angle of the left scapula.

Pulmonary obstructive murmurs are heard with great intensity in the second left intercostal space at its inner end (pulmonary area), and can be traced outwards in that space, and upwards towards the left clavicle.

Pulmonary regurgitant murmurs are heard at the junction of the third left costal cartilage with the sternum, and thence downwards over the right ventricle, along the left border of the sternum.

Tricuspid obstructive murmurs are sometimes heard, with a pre-systolic or mid-diastolic rhythm (like mitral obstructive murmurs) at the left side of the sternum, over its junction with the fourth costal cartilage.

Tricuspid regurgitant murmurs are heard at the lower half of the sternum, over an area corresponding pretty closely to the part of the heart left exposed between the two lungs; but they are often limited to the base of the ensiform cartilage (tricuspid area).

The murmurs due to congenital defects in the heart and aortic aneurysm are described later.

The Character of the Murmur. The quality of the sound is most often blowing; it is sometimes rushing, sawing, or rasping. Sometimes murmurs have a distinctly musical quality. Half-detached fragments of valve playing in the blood current, perforations in valves, and loose chordæ tendineæ sometimes cause such murmurs. In some cases a murmur, though not strictly musical, has a different pitch at one point from that which it has an inch away.

Murmurs vary with the position of the patient, probably from the effect of gravity upon the velocity of the blood currents. Thus in the recumbent position there is often an increase in the loudness of aortic, mitral and tricuspid systolic murmurs. Conversely the erect position often intensifies mitral obstructive and aortic regurgitant murmurs; but there is no hard and fast rule.

The Significance of Murmurs. It is a remarkable thing that, considering the large changes in calibre of the passage through which the blood goes—veins, auricle, ventricle, artery—no murmurs are usually produced in the heart. It is easy to imagine that a small alteration of no pathological importance might make all the difference, and cause a murmur.

As the result of experience gained in the War, especially by Lewis and his co-workers, views on the importance of murmurs have changed considerably. Where diastolic murmurs are present, indicating aortic regurgitation or mitral stenosis, the practice is not to place the man in a high category for service. However, the presence of a systolic murmur should be entirely disregarded, since it has been found that the proportion of men who eventually turn out to be unfit is the same among those who have a systolic murmur as among those who have no murmur at all. No doubt the reason of this is that systolic murmurs heard in apparently healthy men may sometimes be exocardial, but where actual mitral regurgitation is present the lesion may be so well compensated that there is no detectable difference in the heart's efficiency, in the absence of other symptoms.

Murmurs not Dependent upon Actual Disease of either of the Four Valvular Orifices. The above descriptions apply to the sounds which result from obstructions and leakages at the four valvular orifices. But abnormal sounds may be heard over the præcordial area, which arise in other ways. Some of these are called *functional murmurs*, to contrast them with those due to structural disease of the heart.

Hæmic Murmurs. In anæmic states such as chlorosis, pernicious anæmia, and after great losses of blood, a systolic murmur is heard over the cardiac area. It is often harsh in quality, and is heard loudest in the second left intercostal space,

and is traceable outwards along that space and towards the left clavicle—that is to say, in the direction of the flow of blood in the pulmonary artery. This murmur is often loudest in the recumbent position, and diminishes or even disappears when the patient stands up. In severe anæmia a murmur may also be heard at the apex, and also behind. A possible explanation is that the increased velocity of the blood stream from the increased “minute volume” in anæmia causes turbulent motion or gives rise to the murmur.

Exocardial Murmurs. These are sounds of blowing character which are caused not by changes in the interior of the heart, but by sound vibrations produced outside the heart. Some of these are due to the alteration in size of the heart at each beat, which causes movements of the air in the neighbouring part of the lung, and so gives rise to a series of short respiratory sounds with a cardiac rhythm (*cardio-pulmonary*). The most common of these is a short, high-pitched, systolic murmur, often limited to the apex, which is heard in nervous or excited persons when they are under medical examination. Such a murmur is sometimes heard at the left scapula behind, as well as in front. Its exocardial origin is by some thought to be proved, if it disappears on firm pressure with the stethoscope. But pericardial friction sounds, which are certainly produced outside the heart, and may be mistaken for internal bruits, are often increased by pressure. A systolic apex murmur, audible only during inspiration, or as long as the lung is kept expanded, is probably often cardio-pulmonary.

Other exocardial murmurs are produced by displacement of the heart, as when it is compressed by pleural effusion, or by deformities of the thorax; and others by morbid conditions of the lung and pleura immediately adjacent to the heart, and mostly on the left side. Very extraordinary murmurs are sometimes heard when a large pulmonary cavity is in close contact with the heart, the air being driven suddenly out of the cavity with each cardiac impulse.

Friction Sounds. Rubs or friction sounds are exocardial sounds arising from the movement of inflamed and roughened pericardial surfaces over one another during the heart's movements. In character, they are generally rough and grating, and hence are readily distinguished from the blowing murmurs above described. The pericardial rub may be a single sound during systole or a double sound, one in systole and one in diastole; or it may be a triple sound of a shuffling character which is very distinctive. It is not usually in time with the heart sounds. It commences at almost any part of the præcordial area, and may spread over the whole of it. It is sometimes rendered louder by pressure of the stethoscope. Pleuro-pericardial friction has already been described.

ESTIMATION OF THE CAPACITY OF THE HEART FOR EFFORT

The most important of all examinations of the heart is the estimation of its reserve power, by which is meant finding out its response to exercise. In its simplest form this consists in asking the patient to take some exercise, such as walking quickly, running along the level or upstairs, or doing some simple exercises with dumb-bells, and observing whether he is abnormally breathless or exhausted after it, whether he becomes pale, whether his expression becomes anxious, and whether he develops anginal pain. The history of the patient is also of great importance in this connection, as, for instance, that from a boy he was never able to join in games at school, or that since an attack of rheumatic fever or influenza or diphtheria he has never been able to run; or that he never does run for a train, because he gets too short of breath; or that he never runs upstairs, and so on.

The response to exercise bears little relation to the loudness of the murmurs. This fact was observed when recruits were being examined for the army. Many men were found with loud præcordial murmurs who had always believed themselves healthy, with hearts which responded to exercise perfectly normally. On the other hand, in cases of aortic regurgitation the most severe cases often have

the softest murmurs. Estimating the size of the heart and its shape and the extent to which the muscle is hypertrophied will give a better measure of the extent of the lesion which has to be compensated. Palpation and percussion may be employed, but the most certain information can be obtained by the X-rays. The measurements must be taken orthodiagraphically.

The late Dr. G. H. Hunt, who made a large number of observations on the pulse-rate before and after exercise, believed that it was of value in estimating the cardiac efficiency in disease. The number of heart beats during the first two minutes immediately following the cessation of a given amount of work is measured and compared with the pulse rate at rest by taking the ratio. Thus, supposing the pulse rate at rest was 70 and after exercise 160 beats were counted, the ratio would be 2.29. The exercise consists in going up and down a step 13 inches high. In normal trained individuals who carry out this exercise thirty times a minute for three minutes the pulse ratio is approximately 2.5. The exercise for the patient is so chosen (*e.g.* ten, fifteen or twenty steps a minute for three minutes) that the pulse ratio is found to be 2.5. Suppose the rate was 20, then the efficiency is calculated on $\frac{2}{3}\%$, *i.e.* $\frac{2}{3}$ the normal. It is, however, advisable also to take into account the rate at which the pulse falls after the exercise.

EXAMINATION OF THE HEART BY MEANS OF X-RAYS

By this means the size of the heart can be accurately determined. The method is of special importance in cases of emphysema, where percussion is usually not trustworthy. Since the rays come out from a point by reflection from the anticathode, they are not parallel, and so the shadow on the screen is larger than the heart actually is. To correct this the heart must be measured "orthodiagraphically." The diaphragm is stopped down, and the tube is moved about so that the edges of the heart are seen and marked in the middle of the narrow field on the screen.

Another method is to place the patient 6 feet in front of the tube and take a radiogram. At this distance the divergence of the rays will not be sufficient to cause any serious error.

Although examination of the heart by X-rays is a big subject, and cannot be dealt with here fully, a few of the more important points may be mentioned.

In Fig. 12, I. represents the shape and topographical anatomy of the normal heart. Note that the aortic arch forms a prominent knuckle projecting above to the right.

II. represents the normal with the patient in the right anterior oblique position, the rays coming through from the back.

In Plate 11 (mitral stenosis) the shape is characteristic; there is no aortic knuckle as in the normal and the dilatation just below is not due to dilatation of the left auricular appendix, which is always quite small, but to the infundibulum of the pulmonary artery, which is dilated and often forms a projection, but the left ventricle is smaller than usual; hence, the apex tends to be pointed, and the left border of the heart is more vertical than usual. The auricles are dilated and this is well seen in the oblique position, as in II., after swallowing barium; the œsophagus becomes curved. The left auricle is often very dilated (aneurysmal dilatation) and extends further to the right than the left auricle.

In Plate 12, A, which represents a case of compensated aortic regurgitation, the left ventricle is rounded and the apex displaced downwards and outwards. There is excessive pulsation at the apex. The aorta is dilated and the knuckle very prominent.

In pure congenital pulmonary stenosis the right ventricle is hypertrophied and the right auricle dilated, and the left ventricle is displaced upwards and is quite small (Plate 12, B). There is very often a dilatation of the origin of the pulmonary artery, but the cause of this is obscure. When there is also deficiency of the septum the shape of the heart is normal, though it may be large.

dizziness, disturbances of vision, nausea, vomiting and pyrexia. The drug must certainly be stopped if there are signs of heart failure. When the auricular fibrillation has been abolished it is as well to continue with small doses of quinidine (0.8 gramme per diem) for some weeks; the amount can be gradually reduced and the drug eventually omitted. A relapse, which is not uncommon, should be treated along the same lines.

In general, patients feel more comfortable when the heart's rhythm is normal, and for this reason there is an advantage in quinidine over digitalis, which does not abolish fibrillation. Quinidine may be given both in permanent and in paroxysmal auricular fibrillation. Thyro-toxic fibrillation cases do well with quinidine if the hyper-thyroidism has been efficiently treated. Quinidine and digitalis should not be given simultaneously.

PULSUS ALTERNANS

In this form of abnormal heart beat there is a regular alternation of small and large beats, but, unlike the pulsus bigeminus, or coupled beats, in which the interval following the smaller beat is longer than that following the larger beat, the intervals throughout are almost exactly uniform. If the difference between a small and a large pulse beat is not very marked, it may be unrecognised by the finger, and the sphygmograph may be necessary to demonstrate the condition. If the difference is pronounced, that is, if the alternate weak beats are very small, they may be missed by the finger, and the pulse may be thought to be abnormally slow, that is, slower by one-half than it actually is. The condition may also be recognised by taking the blood pressure with a sphygmomanometer. At a certain pressure the weaker beats are eliminated, and the pulse at the wrist apparently drops to half its original rate. Pulsus alternans is not so readily diagnosed from the electro-cardiogram; but in Fig. 31, III., on p. 240, it is present, as shown by the alternate lessening of the R.S. excursion.

This abnormality is certainly due to defective contractility or exhaustion of the myocardium; it is increased or made manifest by exercise; it may be temporary and disappear. But if it is continuous it points to a persistent cause for the defect of contractile power, as, for instance, myocardial degeneration. Experience shows that pronounced cases rarely last more than two years, and not infrequently death is sudden. The prognosis is worse if alternation is observed when the pulse is slow. It is not so bad if the condition only appears when the heart is beating rapidly.

Treatment. The heart must be rested in order to conserve its power. Digitalis has been found of value in those cases where the pulse is quick, especially if oedema is present. Its administration slows the pulse and abolishes the alternation.

INFREQUENT ACTION

(Bradycardia)

Although seventy in the minute is often regarded as the normal frequency of the radial pulse and heart, a pulse of sixty per minute is quite common. A pulse of fifty is normal in some individuals, and the rate in these slow-pulsed persons may fall to forty-eight in the cold hours of midnight or early morning. A slow pulse rate is observed in starvation or under-nutrition, and is, no doubt, associated with the lessened metabolism that occurs.

In examining for this condition it is, of course, essential to observe the heart as well as the radial pulse, as there are several conditions in which the beat of the heart may not get through to the wrist, such as pulsus alternans or pulsus bigeminus. Bradycardia might be suspected if the pulse only were felt, whereas the heart would be beating at a normal rate.

Many conditions of bradycardia are due to vagal stimulation, which may be produced reflexly. The slow pulse of cerebral compression, jaundice, conva-

lescence after influenza and other acute infective diseases is due to this. The same is the case with the slowing of the whole heart that causes the fainting attack so commonly due to emotion or prolonged standing, and possibly the fainting attacks in aortic disease.

The alternate slowing and quickening of the heart during respiration (sinus arrhythmia) is also due to vagal action, and the rather uncommon "phasic irregularity," where the whole heart slows periodically, independently of respiration and without apparent reason.

Sino-auricular block is another uncommon condition producing bradycardia, but sino-auricular block itself may be due to vagal stimulation. A fairly common cause of prolonged bradycardia is to be found in auriculo-ventricular block, especially where the block is complete.

VENTRICULAR FIBRILLATION

By means of the electro-cardiograph the condition of fibrillation has been recognised as occurring in the ventricle as well as in the auricle.

It is observed as a rule immediately before death, though not necessarily as the cause of death; but in animals, and on rare occasions in man, it has ceased in time for recovery to take place. It appears to be the cause of death in lightning stroke, and is believed by some to be the explanation of some of the fatal cases of chloroform anæsthesia.

COMPENSATION OF THE HEART

In disease the heart frequently works under some disability. When by natural processes the strength of the heart is increased to overcome the disability, the heart is said to be *compensated*. The strength of the heart is increased by increasing the thickness of the muscular walls; this is called *hypertrophy* which may or may not be associated with dilatation of the cavities as well.

When the disability under which the heart is working is small, hypertrophy will take place to such an extent that, whatever work it is called upon to perform, its response will be as effective as in a normal person. The patient will not become more than usually short of breath after the severest forms of muscular exercise, and the breathlessness will disappear as quickly as usual after the exercise is finished. Such a disability may be said to be *fully compensated*.

If the disability, which includes damage to the heart itself, is of a higher grade, the patient may be comfortable when at rest or during mild exercise, but may become more than normally short of breath when the exercise is more severe, and this breathlessness may persist for some time. In this case the heart is compensated for mild exercise, but is uncompensated for severe exercise. The term *partial* or *incomplete* compensation may be used for such a case.

In still more severe cases, where the heart is failing, the patient exhibits breathlessness and other symptoms, even when lying at rest in bed. In this case complete failure of compensation has occurred, and the various chambers of the heart become dilated to a greater extent than they were previous to the failure of compensation.

HYPERTROPHY

Hypertrophy is the natural response of the body to an increased amount of work thrown upon the heart, and can take place so long as the nutrition of the muscle is well maintained by a proper supply of blood. When hypertrophy of the ventricles takes place without increase of the corresponding cavities (dilatation) it is called *concentric hypertrophy*, and this may be left-sided or right-sided, depending on which side of the heart this extra work falls, or both sides may be equally affected. The causes of left-sided hypertrophy without dilatation of the left ventricle are—(1) disease of the aortic valves with narrowing of the orifice;

so as to leave some residual blood, but nothing is known for certain about this in man, although it may occur experimentally in the "heart-lung preparation" (Starling).

Pathology. There are two kinds of dilatation. (1) There is the compensatory dilatation of aortic and mitral regurgitation, due to the fact that the particular chamber of the heart accommodates the extra quantity of blood that regurgitates, as well as the normal quantity that is delivered to it from the lungs and is sent on into the general circulation. This is compatible with a perfectly healthy myocardium. (2) There is the dilatation due to yielding of the ventricular walls that spells the onset of failing compensation and is often associated with myocardial disease (*q.v.*). Starling's experiments suggest that this second type of dilatation may also be a compensatory mechanism, enabling the heart to beat more forcibly because the greater the relaxation of the cardiac muscle-fibre, the stronger the beat. This is called the "Law of the Heart."

Slight dilatation of the heart occurs normally during muscular exercise, the effect of this being to increase the output of blood at each beat. It is, however, quite certain from X-ray evidence that immediately after exercise the heart normally contracts down so as to become slightly smaller than its resting size. On the other hand, it has been found that in cases of incipient cardiac failure the heart shows dilatation after muscular exercise.

Morbid Anatomy. The effects on the size and shape of the heart vary with the cavity concerned. In general dilatation the heart becomes more globular, and is widened transversely. The dilated left ventricle increases to the left; when the right ventricle is much dilated, the triangular shape of the heart is lost, it becomes more globular, and the apex is formed partly by the right ventricle instead of being formed entirely by the left. The thickness of the walls will depend on the presence or absence of accompanying hypertrophy. In dilatation with thinning, the ventricular walls may be reduced to $\frac{1}{8}$ inch, and even less at the apex, which is commonly the thinnest part. The auriculo-ventricular orifices share in the dilatation, and incompetence of the valves often results. The auricles may undergo very considerable dilatation, and this is often accompanied by some hypertrophy of the auricular walls.

Physical Signs. The increased size of the heart, as indicated by enlargement of the præcordial dulness or of the shadow of the heart produced by X-rays, may be due to hypertrophy or dilatation or both of these combined. However, it is probable that any considerable enlargement of the heart observed by these methods is chiefly due to dilatation. Any enlargement to the right of the sternum is due to auricular dilatation, because the auricular wall, even if hypertrophied, is quite thin; and it is nearly always *right* auricular dilatation. But in several cases of mitral disease, with enormous enlargement of the left auricle, the latter has actually formed the right border of the heart (11); because the left auricle always enlarges towards the right. It is often possible to feel the beat of the heart by placing the fingers in the intercostal spaces over the dilated auricle. Dilatation of the left auricle may cause dysphagia by pressure on the œsophagus and apparently, in one case seen by the writer, paresis of the left diaphragm by pressure on the left phrenic nerve. It may compress the lower part of the left lung or the left bronchus, or cause paralysis of the left vocal cord. The left auricle may be observed on the X-ray screen when the patient stands in the oblique position, facing the tube, with his right shoulder towards the observer. The rays pass through the posterior mediastinum, between the vertebral column and the left auricle. The œsophagus, if outlined with barium, is seen to be displaced.

Dilatation of the ventricles causes an increase of the præcordial dulness and of the X-ray shadow to the left of the sternum. In extreme cases the shadow reaches the left wall of the chest, and the impulse can be felt in the axilla; but it may be diffuse and weak. Dilatation of the left ventricle is often accompanied

by a systolic murmur, due to mitral regurgitation, and dilatation of the right ventricle often causes tricuspid regurgitation.

FAILURE OF COMPENSATION

Failure of compensation may affect both sides of the heart simultaneously, or may be right-sided or left-sided ; the recognition of the latter is comparatively recent.

Pathology. X-ray observations on the healthy subject have shown that there is more blood in the heart and lungs at the end of inspiration than at the end of expiration, and that the heart and lungs become engorged with blood on attempting a forcible inspiration with the glottis closed (Müller's experiment), and emptied of blood on attempting a forcible expiration also with the glottis closed (Valsalva's experiment), as shown in Plate 13. These observations can only be explained by temporary inco-ordination between left and right ventricles. Normally, over a given time, the output of the right ventricle into the lungs must be equal to the output of the left ventricle into the systemic circulation, or else the lungs would either be deprived of or engorged with blood. Deprivation takes place in Valsalva's experiment, because the right ventricle has to act against the high positive pressure in the lungs and temporarily fails relatively to left ventricle. In Müller's experiment the right ventricle is helped by the negative pressure and more blood is pumped into the lungs than can be disposed of by the left ventricle. This engorgement indicates relative left-sided failure.

Observations on a patient with myocardial degeneration by means of a closed circuit respiration apparatus have shown that such an engorgement of the heart and pulmonary circuit, due to acute left-sided failure, took place during muscular exercise and disappeared again within the first minute or two of rest—a state of affairs which was relieved by treating with oxygen (10). It has been suggested that an acute left-sided failure of this nature is comparatively common and leads reflexly by vagal action to spasm of the bronchi, and in extreme cases, when pulmonary oedema has followed the congestion, to prolonged rattling expiration interrupted by short inspiratory gasps; this is a protective mechanism because the prolonged expiration increases the pressure in the lungs, hindering the relatively over-active right ventricle, while the extremely dangerous period of lowered intra-pulmonary pressure is made as short as possible.

Morbid Anatomy. In *left-sided failure* the lungs are affected. In early stages there is simply undue fulness of the venous radicles in the lung ; there is often, in addition, a transudation of serum into the air vesicles and minute bronchial tubes, so that on section of the lung a quantity of yellowish or almost colourless frothy liquid flows from it ; and in advanced cases the most affected parts of the lung become solid, tough, airless, dull brown in colour, from the presence of hæmatogenous pigment, and uniformly smooth. This condition has been called *heart-lung*, or *brown induration*. Both induration and ordinary oedema especially affect the bases of the lower lobes. As a result of local interference with the circulation, some transudation of fluid into the pleural cavity (hydrothorax) often occurs, and there is more or less proneness to inflammatory lesions of the lung, either in the form of bronchitis, pneumonia, or pleurisy. None of these effects is necessarily bilateral ; the exudations tend to affect the side on which the patient most often lies.

In *right-sided failure* there is a general oedema of the subcutaneous tissues called *anasarca*. In the horizontal position the congested and dropsical area begins in the trunk and tends to spread peripherally as the blood increases in volume. There is also *ascites* and peritoneal dropsy. In the upright position the veins of the trunk are relieved to some extent of their accumulated blood by gravity at the expense of the legs, which thus become a part of the congested area, and the ankles swell by increased output. The head and upper parts shrink

from increased lymph absorption. In the same way if the head and arms hang down these parts swell and the legs shrink. In a very advanced case the congested area has extended up the legs, so that both legs all the way up and the abdominal wall are enormously swollen. In fact, the veins of nearly the whole of the body may be thus affected. It looks as if the body employed this method of storing up superfluous fluid to protect its vessels against abnormal plethora, since the kidneys cannot get rid of it owing to their congested condition (54).

The hepatic veins open into the inferior vena cava so close to the right auricle that the influence of cardiac disease upon the circulation of the liver can be readily understood. The organ enlarges considerably, and becomes darker in colour, and in advanced conditions acquires a peculiar appearance of red, yellow, and white mottling, to which the name of *nutmeg liver* has been applied. On section the centre of each lobule is seen to be occupied by the enlarged hepatic vein rootlet transversely divided, and the adjacent central zone of the lobule is dark red or purple; outside this is a zone of yellow colour from the retention of bile within it; while the external zone of the lobule is of white or grey colour which the microscope shows to consist of cells in a state of advanced fatty degeneration.

The kidneys are congested, becoming in consequence larger and dark-coloured; but from long-continued congestion a certain amount of fibrous tissue may develop, and by its irregular distribution and contraction it may produce a granular condition of the surface.

The spleen becomes hard and darker than normal, and, though varying in size, is often small. The congestion of the stomach and intestine, like that of the spleen, is, of course, secondary to that of the liver, since the veins derived from these organs empty themselves into the portal vein. The mucous membrane becomes congested, and after death considerable distension of the vessels, and sometimes hæmorrhages into the substance of the mucous membrane, may be seen.

DISEASES OF THE MYOCARDIUM

MYOCARDITIS

Myocarditis, or inflammation of the muscle of the heart, may be either acute or chronic. *Chronic myocarditis* can only be recognised in its final stage of fibroid change, and is included in the description of fibroid degeneration (see next page).

Acute myocarditis occurs mostly in connection with pericarditis or endocarditis as a part of rheumatic fever and is described later. But the myocardium may be affected in any acute fever, the symptoms due to diphtheria (*q.v.*) being very characteristic. A more local inflammation of the myocardium results from coronary thrombosis and from malignant endocarditis, where ulceration of a valve extends to its base, and then invades the muscle; or where vegetations or semi-detached fragments set up ulceration in adjacent parts of the endocardium by friction or contact, and this involves the myocardium.

A third form is *suppurative myocarditis*, which is chiefly the result of pyæmia. Small abscesses occur in the substance of the heart, mostly in the wall of the left ventricle, and may approach so near to the pericardium as to rupture into its cavity and set up acute pericarditis. This form of myocarditis is often secondary to acute osteomyelitis, and the treatment is that of the primary disease, but the prognosis is practically always hopeless.

MYOCARDIAL DEGENERATION

Pigmentary Degeneration. (*Brown Atrophy of the Heart*). The heart is smaller than normal, and the muscular fibre, instead of having a full red colour, is of a dull brownish-red, and softer and more friable than is natural. Under

the microscope the fibrillæ are seen to contain a number of minute yellow granules. It occurs in senile and cachectic conditions, being common in fatal cases of malignant disease of other organs.

Fatty Degeneration. This change in the muscular fibres must be distinguished from the deposit of fat about the heart. In the latter the ordinary adipose tissue is deposited beneath the pericardium, and invades the muscular fibres because the connective tissue cells between the fibres become loaded with fat. In the former, or true fatty degeneration, the muscular fibrillæ themselves are the seat of minute fat granules, which replace the true sarcous elements and rob the muscle of so much of its contractile tissue. This true fatty degeneration occurs in different forms: the muscular wall may be uniformly affected, or the fatty changes may be limited to a small patch, or to the layer underlying the pericardium, as described under Myocarditis, or it may consist of streaks and lines on the inner surface of the heart. When the affection is general the heart is of softer consistence, more easily lacerated, of pale pink or buff colour, and often somewhat larger than normal, from yielding of the affected muscular tissue. When the fat is deposited in lines or streaks it gives a characteristic appearance, the lines of pale yellow colour being often arranged upon the darker red muscle, like the markings of a tabby cat. They are seen mostly on the muscoli papillares, on the posterior wall of either ventricle, and on the septum in the right ventricle. Fatty degeneration is common in hypertrophied hearts, and may be present even when the muscle has quite a normal colour.

Ætiology. The causes of fatty degeneration of the heart are general and local. It may be the result of a general tendency to degeneration, such as occurs at an advanced age, and is accompanied by obstruction of the coronary arteries due to atheroma or syphilitic changes, by which the nutrition of the heart wall is impaired. On the other hand, fatty degeneration is seen constantly in pernicious anæmia, and often in other forms of anæmia, in purpura and scurvy, and in cachectic conditions, such as phthisis and cancer; in poisoning by phosphorus, by some mineral substances (lead, antimony, arsenic), and in chronic alcoholism. In most of the acute febrile diseases the consistency of the heart is sometimes altered, as the result of a finely granular condition of the muscular fibres, which is probably not to be separated from fatty degeneration. This is the case in enteric and typhus fevers, in yellow fever, diphtheria, small-pox, and measles. Fatty degeneration also arises from myocarditis, and is seen in connection with long-standing valvular disease and renal disease.

Fatty overgrowth or infiltration of the heart has previously been described as a separate disease, in which not only is the outside of the heart loaded with fat, but fatty streaks are seen penetrating into the muscle wall. This is characteristic of *obesity* and is described under this head.

Fibroid Degeneration. In this form of degeneration, the muscular tissue of the heart is replaced by white fibrous or connective tissue. The change is in most instances partial, so that streaks and patches of a white, yellowish-white, or grey colour are seen deep in the muscular substance. It affects the lower third of the ventricle, the lower third of the septum, the muscoli papillares, and sometimes the bases of diseased valves. Only occasionally is the ventricle almost entirely converted into fibrous tissue, but even here some traces of muscular fibre may be found on microscopical examination. The heart affected with fibroid disease is generally hypertrophied, and it may be dilated, or the subject of adherent pericardium; the affected part of the heart's wall is often thinner than normal, and it may be bulged out into a distinct aneurysm.

Ætiology. Fibroid degeneration often results from rheumatic myocarditis, and in more pronounced cases the co-existence of pericardial or endocardial lesions will sometimes show its inflammatory origin (*chronic myocarditis, interstitial myocarditis*). On the other hand, fibrosis of the heart is often due to obstruc-

tion of the coronary arteries, and may be associated with fatty degeneration. In these circumstances the blood supply is insufficient for the nutrition of active muscle. The latter atrophies, and is replaced by fatty or fibrous tissue. If the coronary obstruction takes place fairly quickly, fatty degeneration occurs. If the obstruction is more chronic, fibroid change predominates. Fibrosis may also be secondary to coronary thrombosis or infarction. It is also commonly associated with chronic bronchitis, emphysema, Bright's disease, and arteriosclerosis. Fibroid degeneration may be due to alcoholism or long-continued congestion.

Syphilis. The lesions of this disease occur as arteritis, as fibrous scars (*syphilitic myocarditis*), as fibroid masses, or as a distinct gumma, which may be cheesy, and even softening in the centre, affecting the muscular substance of the heart in the same way as the voluntary muscles and causing some surrounding inflammation. A gumma is seated usually in the walls of the ventricles. It produces no characteristic symptoms apart from those considered under the heading of Myocardial Degeneration. Sometimes the A.-V. bundle is affected, leading to Adams-Stokes' syndrome.

Tubercle. Tubercles not infrequently form in connection with inflammation of the pericardium, when they are found as whitish-grey or yellowish granulations, mostly in the substance of the pericardial lymph or false membrane uniting the layers of the cavity, or sometimes actually under the layer of the visceral pericardium. They occur in the course of general tuberculosis, and there may be secondary advanced tuberculosis elsewhere. The diagnosis can only be made from the appearance of pericarditis in those circumstances; but it must be remembered that a pericarditis, which is not tuberculous, may also arise in the course of phthisis. Isolated deposits of tubercle are exceedingly rare.

Symptoms of Myocardial Degeneration. In early cases the patient complains of breathlessness on exertion. There may be præcordial pain, which may be noticed after exercise, or there may be definite anginal attacks. The patients may suffer from cerebral attacks, with unconsciousness and convulsions, but these attacks are probably due to some abnormality of the cardiac mechanism, such as heart block, or vagal stimulation. Appetite is often poor, and the patient may complain of indigestion. Sometimes these are the only symptoms complained of, and on inquiry the history of shortness of breath on exertion points to the heart as the primary cause of the gastric symptoms.

The physical signs attributed to myocardial degeneration are feeble cardiac impulse with faintness of the first heart sound, which may become equal to or less than the intensity of the second sound over the aortic area. This diminution of intensity gives a tic-tac character to the sounds when examined with a stethoscope, and this is further emphasised by a relative shortening of the diastolic interval, so that the sounds become more evenly spaced. The heart is dilated.

The symptomatology of a group of cases showing myocardial changes has been very carefully studied (12). The cases are met with very commonly. The patients are elderly, and suffer from shortness of breath, coming on at first after exertion, but later on they are more or less permanently dyspnoic. In some cases there is Cheyne-Stokes breathing, and in some other cases there are sudden attacks of extreme breathlessness, which come on particularly at night-time, and which are described by the term *cardiac asthma*; these attacks of paroxysmal dyspnoea may often be the dyspnoic phase of a rather irregular Cheyne-Stokes breathing. There may or may not be orthopnoea present. Cyanosis is conspicuously absent, and if present at all its amount could hardly be considered enough to account for the dyspnoea. The rate of the heart is usually increased. The mechanism of the beat may be normal, but common irregularities such as those due to heart block, auricular fibrillations, extra-systoles, and alternation may be present. The heart is increased in size. Murmurs

may be present. The body temperature tends to be subnormal. The advanced signs of cardiac failure, such as anasarca, congestion of the lungs and liver, may be present. There is usually some retention of urea in the blood, but the values are not extreme—at most 0.1 per cent., and usually 0.05 per cent. (normal 0.03). Albuminuria with casts may be present and unless there are signs of venous stasis, the urine is increased in volume. Post-mortem examination shows that there is advanced coronary sclerosis of the heart, and there may be fatty degeneration. The kidneys show thickening of the vessels and some fibrosis, often of a patchy nature. The glomeruli are often congested, and some are hyaline, but there is no extensive obliteration of glomeruli, as occurs in chronic interstitial nephritis when the patient has died from uræmia. Sometimes these patients are described as cardio-renal cases, but it seems clear that although the kidneys always show some changes, and are termed senile arteriosclerotic kidneys, these are not the essential cause of the disease. The urea retention never reaches a fully uræmic figure of 0.2 or 0.3 per cent. Hence they are best described as cases of myocardial degeneration, giving rise to cardiac asthma or paroxysmal dyspnoea.

The CO_2 in the arterial blood is increased in the dyspnoëic cases, and the oxygen content of the arterial blood may be low. Consequently, it has been suggested that the dyspnoea, which may be extreme, is brought about by bronchial spasm (14). On this view, the term *asthma* can be used for this type of case. However, in pure cardiac dyspnoea, *e.g.* mitral stenosis, and when there is Cheyne-Stokes breathing, the CO_2 is low from increased respiration (41), although in some cases it may be a little raised and the oxygen lowered from pulmonary congestion which hinders the free interchange of gases in the lungs. Recent experimental evidence points to the paroxysm being, at any rate in some cases, caused by acute pulmonary congestion and œdema from relative failure of the left ventricle (13). The **Treatment** is considered on p. 276.

RUPTURE OF THE HEART

Apart from injury, this is mostly a consequence of fatty degeneration or fibroid changes; these may be coronary thrombosis leading to hæmorrhage into the myocardium and destruction of part of the wall of the heart; in a very small proportion of cases, its cause is abscess, malignant endocarditis and aneurysm. It occurs in old people, and not infrequently follows muscular efforts. The left ventricle has been the seat of the rupture in three-fourths of the cases on record. The patient is suddenly seized with intense cardiac pain, followed quickly by pallor, unconsciousness, a few convulsive twitchings, and death. In rare cases life has lasted some hours, or even days, with pallor, cold sweats, feeble pulse, and sighing respiration.

ANEURYSM OF THE HEART

Aneurysms of the heart may be acute or chronic.

Acute aneurysms arise from ulcerative endocarditis of the ventricle wall, in the manner which will be described under Malignant Endocarditis, and this is a rather frequent cause of aneurysm of the *pars membranacea septi*, or undefended space, as well as of the valves. Aneurysms of the *pars membranacea* are sometimes congenital. In either case, the sac opens towards the left ventricle. The condition is not recognisable during life.

Chronic aneurysms of the heart commonly arise in connection with fibroid degeneration. The cavity affected is weakened at one spot by this conversion of its muscular fibre into fibrous tissue, and dilates under the pressure of the blood into a sac. The left ventricle is their usual seat, and only a few cases are on record of aneurysms of the other three cavities. In two cases out of three they occupy the apex; they form rounded sacs, of which the communication from the

is no invasion of the blood stream by the streptococcus, and by the time the acute rheumatism begins on the 16th day the streptococcus has disappeared from the throat, though in fatal cases of pericarditis it has been grown from the spleen and pericardial lymph glands (50). This sequence of events would be compatible with the view that the acute rheumatism was an allergic manifestation due to "sensitisation" during the original streptococcal attack; but it might also be argued that the hæmolytic streptococcus was not itself the primary cause of the acute rheumatism, but facilitated the introduction of a secondary invader, for instance, an ultra-microscopic virus, which was the direct cause of the disease; there is recent evidence of this.

Morbid Anatomy. The chief structural changes of rheumatic fever result from carditis, polyarthritis, chorea and subcutaneous nodules. The reaction, which consists in the formation of an inflammatory node, is essentially the same in all these cases, though the appearance depends on the locality affected. The reaction is most easily studied in the heart.

Acute Myocarditis. The first change occurs in an arteriole; at one point the lining cells swell and multiply and become the centre of a brisk inflammation with round cell infiltration, chiefly polymorphs. The arteriole becomes sealed with clotting and destroyed. Later the round cell infiltration disappears, and we get eventually a group of large multinucleated cells embedded in a background of fibrin constituting the *Aschoff's node*. These cells are fibroblasts and are later converted into ordinary fibrous tissue, forming a permanent but inconspicuous scar. In the muscle fibre cells fatty granules and droplets appear first of all near the nucleus, and later there is localised necrosis which may be toxic in origin or due to cutting off the blood supply when the arteriole becomes destroyed. The nodes appear most commonly in the left ventricle, deeply embedded in the muscle, near the root of the aorta and the mitral ring.

Acute Endocarditis. In rheumatic endocarditis this "nodal" inflammation results in the formation of very slight swellings of subendocardial tissue near the edge of the valves on the auricular side of a mitral cusp, or the ventricular side of an aortic cusp, so as to form a number of beadlike elevations, usually described as *vegetations*; and these occupy at first the line where the valve touches its fellow on closure, and not the free edge of the valve. Later the endothelium of the valves over the inflamed area becomes loosened, and fibrin and polymorphonuclear leucocytes are deposited from the ventricular blood. With subsidence of the inflammation slight scarring again takes place; but in long continued inflammation or after repeated acute attacks gross deformity of the valves is produced, which is described in the section on chronic endocarditis. The appearances of pericarditis are also described later.

Arthritis. The joints have been found in fatal cases to contain a turbid synovia, with shreds of fibrin. Leucocytes are present, but the fluid is never purulent. The synovial membrane itself is vascular, and covered with a layer of lymph. Probably the synovial changes are even slighter than this when such rapid subsidence takes place as is often witnessed. In the tendon sheaths have been found opaque serum and greenish-yellow lymph.

The genesis of the subcutaneous rheumatic node, so characteristic of rheumatism, is exactly the same as that already described for the heart, but on a larger scale. It begins with focal arterial inflammation; then there is multi-nucleated fibroblastic infiltration which evolves into a small scar in the course of a few weeks.

Symptoms. There is often a previous history of one or more attacks of tonsillitis; and the tonsils are seen to be enlarged, or to contain deep crypts, or to exude pus on pressure, or adenoids may be present. The first symptoms of the rheumatism may be those of a multiple arthritis or synovitis, lesions which are obvious because painful and accompanied by pyrexia; in other cases, and especially in children, the first lesion is inflammation of the cardiac valves, myocardium or pericardium (rheumatic carditis), which may be entirely latent

but may be associated with a history of vague pains, perhaps called *growing* pains, which have not confined the child to bed. Sometimes a child attacked by the articular form of rheumatism is found to have a cardiac lesion obviously of old date, not dependent upon the present synovitis, but without any history of a preceding synovitis, or there may have been a history of *chorea* (see later).

The *joints* may be affected quite suddenly. The knee is often first attacked, and then the ankle, in other cases the wrist or the shoulder. Whichever is first attacked, the disease may soon spread to other joints of the body, so that the shoulder, elbow, and wrist, the hip, knee, and ankle, may all be inflamed at the same time or successively. Occasionally in adults the joints of the fingers and toes or the sterno-clavicular joint, or even the vertebral joints, are affected. The extent of the disease is very variable. In one only two or three joints may be inflamed, in another a great number; and an important feature of rheumatic fever is the way in which some inflamed joints will quickly recover while others become involved; and these last will get well while fresh joints suffer, or those first affected become again inflamed.

A joint attacked by rheumatic fever is swollen, hot, tender to touch, and painful. The swelling is most manifest in the knee, where effusion can easily be recognised, in the ankle and in the wrist. The colour may be a bright pink; it rarely covers the whole swelling, and may be in patches. The tenderness is sometimes extreme, so that a slight shock on the bed, and any clumsy handling of the joint, will cause intense pain. It may persist after spontaneous pain has subsided. In the shoulder, hip, and elbow joints, pain and tenderness are the chief evidences of rheumatism, as slight swelling is not easily recognised, and redness is generally absent. On the whole the arthritis is more painful in adults than in children. It is common enough for the muscles of the limbs to be tender on palpation, due presumably to a myositis, which is similar in nature to the myocarditis; in fact, in a boy under the writer's care, there was intense muscular tenderness without any involvement of the joints at all.

In the vast majority of cases the synovitis clears up without leaving any sign of previous inflammation; but occasionally, especially if the same joint is repeatedly attacked, permanent alterations may be seen, with wasting of the muscles. These may be associated with rheumatic nodules, and resemble very closely acute rheumatoid arthritis. Histologically the lesions in rheumatoid arthritis are indistinguishable from those of acute rheumatism, so that it is possible that they may eventually prove to be different manifestations of the same disease. It has been stated that the synchondroses are also sometimes involved in rheumatic fever. Undoubtedly the sheaths of the tendons about certain joints are often inflamed, especially those about the wrists and ankles; and some of the redness that extends on to the dorsum of the foot and hand may be due to their inflammation. In a boy seen by the writer there were subperiosteal nodes round the mandible.

With this multiple arthritis there is associated some *pyrexia* which subsides as the inflammation of the joint subsides and recurs with any recurrence of the arthritis. There is sometimes hyperpyrexia. Profuse *sweating* is a characteristic of acute rheumatism. The sweat may often be seen in clear vesicles at the orifices of the sweat pores, called *sudamina*; when the vesicles contain a point of pus, and are surrounded by a pink areola, they are known as *miliaria*. The fever is not generally accompanied by much cerebral disturbance, and delirium is not a marked feature in uncomplicated rheumatic fever. The *tongue* is furred and the bowels are constipated. The *urine* is scanty, high-coloured, and acid; it contains only occasionally a trace of albumin.

Rheumatic Carditis. In a large proportion—between a third and a half—of the cases of rheumatic fever beginning with arthritis, the *heart* is found to be affected by endocarditis and myocarditis and less often by pericarditis. While the descriptions of the pericarditis is deferred till later, it must be pointed out

that such symptoms of carditis as are present are due to the myocarditis rather than to the endocarditis. They are usually quite slight, and sometimes absent altogether. The onset of carditis may be marked by an increase in the pyrexia. A persistent tachycardia is common. In severe cases there is shortness of breath and exhaustion after exercise, and these may be the earliest symptoms of the disease. Exceptionally pronounced heart failure shows itself within a few months of the rheumatic attack. The patient is often, but not always, anæmic.

The earliest physical sign is represented by a slight prolongation, or roughness, or some want of clearness of the first sound in the mitral area on auscultation. Within twenty-four hours it may lengthen into a distinct murmur, or soft blowing sound, which accompanies, and may later on entirely replace, the first sound. It indicates acute infection of the heart, and is certainly due to mitral regurgitation. There may be minute pin-point vegetations on the valves, but it is difficult to see why these should give rise to incompetence. The more probable explanation is, that, owing to myocarditis, there is dilatation of the mitral ring leading to incompetence. These murmurs may disappear as the patient gets better. The mitral regurgitation commonly leads to an accentuated pulmonary second sound. Acute heart block also occurs, and in some cases a reduplicated first or second sound or a prestolic murmur heard at the apex may be due to the auricles contracting perceptibly before the ventricles in this condition, but all these physical signs may also be due to the rush of blood through the mitral valve as described below. A less common murmur, also heard at the apex, in rheumatic fever in children is mid-diastolic in time. This is certainly not in all cases due to mitral stenosis, as post-mortem examination has on more than one occasion disclosed a healthy valve. It is probably due to "relative stenosis," i.e. a normal valve opening into a dilated ventricle, and so producing a fluid vein and eddies. It is similar to Flint's well-known murmur in aortic regurgitation. The presence of this murmur in children usually means a severe grade of infection, and it often leads on in later years to a fully developed mitral stenosis. If the aortic valve is affected, the second sound may become imperfect, and a diastolic murmur is developed, but this lesion is much less frequent than the others.

Pleurisy is sometimes seen when the heart is severely affected, and especially in association with pericarditis. A rub is heard, and there may be pain. When situated between the pericardial and visceral pleura, pleuro-pericardial friction may be present (see p. 127). There is not usually sufficient exudation to require tapping; but occasionally it may be extensive and give rise to physical signs at the left base, resembling the pressure of a pericardial effusion on the left lung—impairment of note, deficient vesicular murmur, or weak high-pitched bronchial breathing. *Acute pulmonary œdema* and *broncho-pneumonia* occur in children occasionally (Poynton). Acute nephritis not uncommonly occurs simultaneously.

Besides the sudamina and miliaria already mentioned, urticaria and different forms of erythema may occur, especially *E. multiforme* and also purpura (*peliosis rheumatica*). *E. nodosum* is also associated with rheumatism. It may be of streptococcal origin (see later), but is most commonly tuberculous.

Subcutaneous nodes are also more common in children than in adults, and are found in the neighbourhood of joints, and over bony ridges and prominences, where little fat intervenes between the skin and bone—for example, over the elbows and knees. They are not painful and seldom tender; they are freely movable under the skin, and slightly on the fibrous structures beneath them. They disappear in a few weeks.

Course. If untreated, the symptoms in the joints may last from ten to fourteen days, when they will often subside; if treated by salicylates, the pains and fever are often gone within a week. In any case, however, rheumatism shows a great tendency to *relapse*, the joints being affected in a precisely similar manner after an apyrexial painless interval of from two days to a fortnight. Occasionally recovery is delayed by the persistence of the inflammation in one

joint for weeks or months ; pain, swelling, and stiffness are prominent troubles, and the joint has ultimately to be treated, with rest, splints, and local treatment. Another cause of delay in convalescence is the rapid progress of a carditis, so that the patient passes at once from rheumatism into pronounced heart disease, with murmurs of aortic or mitral disease and failing cardiac muscle and even pericarditis. Death takes place in the course of an attack from carditis, very rarely from hyperpyrexia.

Diagnosis. This usually presents no difficulty, the sudden occurrence of joint pains, with redness and swelling, fever and profuse sweating, being mostly decisive, especially if it occurs in young persons with previous good health, or, on the other hand, with a previous history of rheumatic fever or of heart disease. Where one joint alone is affected, *acute osteomyelitis* must be considered. Here the constitutional symptoms are more severe ; there is great tenderness, especially when pressure is exerted on the bone. *Acute pyæmia* with suppurative arthritis is uncommon, and there is usually some obvious focus of infection, such as a septic uterus after childbirth. The joints when attacked take a long time to clear up. *Gonococcal synovitis* is also more persistent than rheumatic fever, and is only rarely accompanied by cardiac complications, and the inflammation particularly tends to involve fasciæ ; but in early stages it may be readily mistaken for acute rheumatism. Acute multiple arthritis may also occur in many specific infections, *e.g.* *enteric fever*, *dysentery*, and *pneumococcal infections*, *relapsing fever*, etc. The reaction of the patient to salicylates is a valuable indication of acute rheumatism. The diagnosis from *gout* will be given with the description of that disease.

The diagnosis of rheumatism in a child who has not had a multiple arthritis depends on the recognition of sore throat or septic tonsils, and a cardiac lesion or chorea. The diagnosis of an acute endocarditis and myocarditis requires some care, as the murmurs of recent acute endocarditis and myocarditis may be confounded with the murmurs of old *valvular disease*, and with *pericardial* friction sounds. The chief point to note is that the murmur in question is generally soft in quality, systolic in time, and strictly limited to the mitral area. There may be tachycardia and an accentuated pulmonary second sound. A functional or hæmic murmur is generally loudest over the pulmonary artery, and often harsh in quality. The murmur of chronic valvular disease is often loud or harsh, heard over a large area, and accompanied by some alteration in the size or shape of the heart.

Prognosis. The immediate mortality of acute rheumatism is small. The possible dangers have been indicated above. The temperature and pulse rate and alteration in the murmurs give the best clinical indications as to whether the disease is still active. The sedimentation rate of the red cells provides valuable additional help. Using Westergren's method, if the cells fall more than 10 mm. in the first hour, or more than 20 in two hours, the disease is still active (42).

Prevention. A clay soil is usually regarded as predisposing to rheumatism, and low-lying situations in river valleys should be avoided. Children who are rheumatic should change their clothing if it becomes damp. The most important point is to treat all possible sources of infection ; in this connection the nose and sinuses and throat should be examined with care, especially in children, while in adults dental infection in particular should be looked for. A study has appeared on the subject of tonsillectomy carried out on eighty-five children with various rheumatic manifestations (43). In most cases the tonsils had been inflamed more than once, and in all cases the tonsillar lymph glands were enlarged. The cases were followed up over an average of three and a half years after tonsillectomy. The tonsillar lymph glands became impalpable in 59 per cent. of cases. Of patients who had had rheumatic fever, there was no recurrence in 84 per cent. As regards chorea, there was no recurrence in 50 per cent. of cases. As regards myositis and joint pains, there was no recurrence in 77 per cent. of cases. In a

few cases a second operation was necessary to remove the tonsils completely. On the other hand, in a series of 428 cases, including chorea, at Great Ormond Street, the beneficial result of tonsillectomy was very doubtful (45), and this agrees with other authorities (47). The following conclusions may be drawn: In rheumatic children complete removal of the tonsils by means of enucleation is desirable when the infection of the tonsils is impairing the child's health and there are repeated sore throats and chronic glandular enlargement; the operation should be carried out after an acute infection has subsided.

Treatment. For the efficient treatment of even mild cases of rheumatism complete rest in bed is absolutely necessary until all pain and swelling of the joints has disappeared and all active inflammation of the heart has subsided. It is difficult to be certain when this is actually the case, so that patients, particularly if they are children, may be kept in bed many weeks to be on the safe side. In any case the patient should not be allowed to get up till the pulse and temperature have fallen to normal and have remained so for some days. Another useful indication is the character of the murmurs. As long as these show any change from day to day it means that there is active inflammation present. Possible foci of infection should be looked for and dealt with (*see p. 276*). Tonsillectomy is dealt with above.

In severe cases the joints will be so painful that the patient cannot do otherwise than lie still. The joints should be protected from every risk of injury. Sometimes it is desirable to raise the bedclothes from the limbs by a cradle; and some local relief to the pain may be obtained by wrapping them round with cotton wool, upon which, in severe cases, a little anodyne, such as belladonna or opium liniment, may be sprinkled, or methyl salicylate (artificial oil of wintergreen) may be spread on the joint and covered with guttapercha tissue. In the past a strict milk diet has usually been prescribed, but on general principles it is much better to allow a more varied dietary, as in other febrile conditions.

The drug now almost universally employed is sodium salicylate. When the patient is fully under its influence the pains disappear, the redness and swelling of the joints subside, and the temperature falls two or three degrees—it may be to the normal. If the drug is then lessened or discontinued, the pains will most likely return; if the dose is maintained, the rheumatism may be practically cured from that time; but the treatment, both by drug and diet, will have to be continued for ten days or more, at the end of which time some relaxation may be cautiously allowed. An efficient dose of either salicylic acid or its sodium salt is 20 grains, and of salicin 30 grains, every four hours during the first twenty-four or thirty-six hours; but in less severe cases a smaller quantity may suffice. Some give a smaller dose every hour for the first four or five hours, and then diminish the frequency to every two hours. If the attack is very severe, it may be desirable to give a 20-grain dose every two or three hours for the first day. If too much is given, the patient suffers from headache, deafness, tinnitus aurium, and slight delirium, which cease when the drug is withdrawn. Occasionally vomiting, a slow or irregular pulse, albuminuria, epistaxis, hæmaturia, or suppression of urine with uræmia has occurred. As a rule, the earlier toxic symptoms coincide with the subsidence of the pains; but, this having been obtained, the frequency of the dose must be reduced to four times or three times a day, at which rate it should be continued until five or six days have elapsed from the last pain or the last abnormal temperature, when the drug may be stopped altogether.

There is no material difference in the effects upon rheumatism of the three drugs under consideration. The sodium salt is generally preferred, and it is frequently combined with an equal quantity of sodium bicarbonate. Sometimes these drugs are not so successful; the pains continue in abated form, or relapses frequently occur. Salicylate of quinine (2 to 6 grains) may then be useful; or recourse may be had to the old alkaline treatment—potassium bicarbonate or acetate, 20 grains every four hours—or to potassium bicarbonate with quinine. Compounds containing salicylic acid, such as salol, salophen, and acetyl sali-

cyclic acid (aspirin), have some influence upon the pains of acute rheumatism. The last has been largely used in 10- or 15-grain doses in cachet.

It is not known at present how salicylates act. Many authorities believe that they have no specific action on the infection itself. It has, indeed, been suggested that there is a disadvantage in abolishing the pyrexia and the joint pains, because an indication of the progress of the infection in the heart is thereby lost, and a certain measure of pyrexia may be a useful defence against the infection.

The treatment of hyperpyrexia must be prompt and energetic, as dealt with under Heat Stroke.

CHOREA

(*Sydenham's Chorea, Chorea Minor*)

Chorea (*χορεία*, a dancing) is characterised by irregular involuntary movements of different parts of the body. The popular equivalent, St. Vitus's dance, has reference to the occurrence in the Middle Ages of epidemics of dancing mania, when patients were cured by a pilgrimage to the shrine of St. Vitus—*Chorea Sancti Viti*. But the complaint in those epidemics partook rather of the nature of hysteria, and though the name *chorea* is still sometimes used to indicate some other forms of abnormal movement, it is, as a rule, reserved for the disorder now to be described.

Ætiology. Chorea is one type of acute rheumatism, and so it has the same ætiology. It is mostly a disease of childhood: nearly half the cases occur between the ages of five and ten, and another third between ten and fifteen. It is more frequent in girls than in boys, in the proportion of two or three to one. Fright or mental shock or strain, such as work for school examinations, may be an aggravating cause of the disease. Among adult patients pregnancy is a common antecedent; some of them have had rheumatism, and others chorea in childhood.

Morbid Anatomy. The brain shows hyperæmia; but there are not enough changes to suggest that bacterial invasion is the cause of chorea. Lumbar puncture rarely discloses any increase in lymphocytes.

Pathology. The facts in favour of chorea being a rheumatic infection are—the frequent occurrence of endocarditis and its almost universal presence in the fatal cases; the association with rheumatic fever and its various manifestations during life.

It seems necessary to give up the view, previously held, that chorea was a bacterial invasion of the brain, except in a few of the worst cases (*chorea insaniens*), where a streptococcus has been cultivated. Recent work points to the disease as being due to a lowered content of ionic calcium in the body and especially in the cerebro-spinal fluid—below 5 mg. per cent.—and this rises to above 5 mg. when the child recovers (51). On this view chorea is closely related to tetany, and, just as in tetany, it is found that the excitability of the muscles to electrical stimulation is increased. Thus the minimum exciting current, enough to produce a visible twitch in the supinator longus, with the active electrode applied to the motor point of the muscle was below 2 milliamperes, the normal being above this figure (52).

Symptoms. The symptoms of chorea may be present alone or may be accompanied by any of the manifestations of acute rheumatism already described. The most prominent feature of the disease is the action of the muscles: they are in a condition of (1) involuntary movement, (2) ataxy or inco-ordination, and (3) slight degree of actual weakness or paresis. The patient is in a constant state of movement, whether lying, sitting, or standing; and the movements, which affect nearly all the muscles of the body, are jerky, irregular, and devoid of purpose. The fingers are opened and shut, the wrist suddenly extended or flexed, or the shoulder lifted. The facial muscles are twitched, the eyebrows suddenly elevated, the head or the eyes rotated to one side, and the chin elevated

or depressed. In the lower extremities the movements are often less ; the toes are twitched, or one knee gives way. In the muscles of the trunk, one notices half-rotation of the body to one or other side, sudden retraction of the abdomen, or jerky action of the respiratory muscles.

The irregularity is more marked on voluntary movements. If the hands are stretched out in front, the child is quite unable to hold them steady ; on protruding the tongue, it is put out with a jerk, and perhaps withdrawn suddenly, and the muscles of the jaws act capriciously at the same time ; in walking the legs are thrown about, the body is jerked round, and the shoulders are lifted. In the same way it may be seen that the muscles relax with great readiness ; after grasping an object, one or two fingers quickly yield, and soon the hand and arm will drop. The movements are increased when the patient is watched, or if she becomes excited ; they cease during sleep.

The child's disposition is apt to be altered ; she becomes fretful, irritable, capricious, or excited, while intellectually she has a weak memory and is unable to fix the attention.

Varieties. Sometimes the symptoms are very slight, and remain so for some time ; the fingers are only twitched a little, irregular movements are scarcely noticed, but the child drops things that she attempts to carry. In some cases the movements are limited to the arm and leg of one side only (*hemichorea*). In others there is decided paralysis, with only slight choreic movements ; the arm hangs by the side, and can with difficulty be raised ; the fingers are twitched occasionally, and the grasp is extremely feeble (*paralytic chorea*) ; there may be a *choreic hemiplegia*. Rarely all four limbs are affected, the child lying quite helpless, while each limb drops like a log on being raised from the bed. Speechlessness, mental weakness, maniacal and melancholic conditions also occasionally occur, and are generally temporary.

Exceptionally the movements are very violent ; standing or sitting is impossible, and the patient is confined to bed, where she throws herself about in the wildest contortions, striking the hands and arms against the sides or head of the bed, and rubbing the elbows, shoulders, buttocks, hips, knees and heels, so as to produce serious abrasions of the skin. Feeding becomes difficult or impossible, as everything placed to the mouth of the patient is jerked aside or spilt ; and even if it gets into the mouth it may be rejected by the want of co-ordination for deglutition. These cases (*chorea gravis*) sometimes progress with great rapidity ; the patient appears to be exhausted by the constant movement and the want of sufficient nutriment ; rapid emaciation takes place, the face is flushed, the eyes sunken but bright, the lips and tongue dry, the pulse rapid, and ultimately death may occur, being preceded often by some rise of temperature and by cessation of the movements. In fact, the patient may lie for some hours before death perfectly tranquil, and give the impression that convalescence has begun. In some the mind is severely affected, and the patient becomes delirious, or even wildly maniacal. Such violent cases are much more frequent in persons between the ages of fifteen and twenty-five, and a large proportion are in pregnant females.

Duration. The duration of chorea is very variable. The majority of cases last from six weeks to three months ; not infrequently slight twitching may occur for many weeks or months after the severer manifestations have subsided, and the symptoms may again after a time become aggravated. In the end most cases recover. The violent cases are usually of short duration ; if death takes place, it is often within two or three weeks from the first symptom, or from the time when the movements become violent ; if recovery ensues, the movements become quieter after a few weeks, though complete cure may be delayed some time. Chorea is very apt to recur even after its entire subsidence ; second and third attacks are frequent. These may be of shorter duration than the primary attack, but are not different in other respects.

Sequelæ. The disease sometimes leaves behind it a liability to sudden

starts, which in the course of months subside. Epilepsy has also been observed, and after recovery a tic may remain.

Diagnosis. This rarely presents any difficulty. Movements closely resembling those of chorea may occur as a part of *hysteria*; they are generally more rhythmical, more localised, and may recover quickly. *Habit spasm* may be present in children, and is closely allied to the above; the movements are localised, voluntary in character, more under control and less constant than those of chorea. There are jerky movements in *Friedreich's ataxia*; but the gait is different, the history is a very long one, and other signs are present.

Prognosis. In children it is favourable, apart from the condition of the heart; in young adults it is much more uncertain.

Treatment. The treatment of acute rheumatism should be consulted. The child should be kept quiet in bed, and everything tending to worry or annoy should be kept from her. The diet should be plain, nutritious, and abundant. Calcium aspirin (7 to 10 grains), and chloretone (5 grains) three times a day are beneficial. Arsenic is usually given, but there is no evidence that it is of any value. In violent cases food may have to be given through a nasal tube. Favourable results have recently been obtained with parathormone injections, which raise the calcium in the cerebro-spinal fluid—5 minims night and morning for a child of ten, 3 minims for a child of three.

ENDOCARDITIS

Endocarditis, like so many other inflammatory processes, is always due to the action of micro-organisms or their toxins. As a rule the parts first affected are the valves of the left side of the heart: the lesion is often confined to them, and may completely subside, or if any traces are left they consist of structural damage to the valve, of which the later consequences are solely dependent on the mechanical failure of the valve. This is a simple *acute endocarditis*, while the term *chronic endocarditis* is applied to the permanent deformities and changes in the valves which result from a simple acute endocarditis and may be made worse by later acute attacks; but the term is also used for an inflammatory process, which is chronic from the beginning. In other cases, more extensive changes take place in the valves, micro-organisms are present and may be conveyed by the current of blood to remote parts of the body, and so set up fresh foci of disease—*malignant endocarditis*.

ACUTE ENDOCARDITIS

Ætiology. Acute endocarditis is, in the great majority of cases, an infection due to the virus of acute rheumatism, which has just been dealt with. Myocarditis is usually associated with it. Acute endocarditis also occurs in scarlet fever, diphtheria, typhoid, and other infectious diseases. It may occasionally occur during the progress of Bright's disease, syphilis and other chronic maladies. It may occur after local injuries, such as the rupture of a sigmoid valve, or of the chordæ tendinæ, and as the result of unnatural friction of one part of the heart with another. The passage of currents of blood through abnormal apertures may cause the local inflammation of the endocardium. In patients dying from any infective disease it is very common to see minute vegetations on the valves, particularly the aortic valves, indicating a terminal infection of the blood stream.

No separate account of acute endocarditis is necessary, as it has been dealt with under acute rheumatism and other infective diseases.

CHRONIC ENDOCARDITIS

(*Chronic Valvular Disease of the Heart*)

Relative Frequency of Valvular Lesions. The relation of endocarditis to the two sides of the heart is of very great importance. If endocarditis occurs

during foetal life, it is believed to attack the pulmonary or tricuspid valves ; but it is extremely rare for endocarditis acquired during life to attack the valves on the right side of the heart *only*. It occurred only once in 20,000 post-mortem examinations at Guy's Hospital. On the other hand, right-sided endocarditis associated with left-sided endocarditis is not so very uncommon (18). The commonest occurrence is for the valves on the *left* side to be affected alone. Disease of the mitral valve is more common than that of the aortic valve, since rheumatic fever, which pre-eminently attacks the mitral valve, is the commonest antecedent of valvular disease. Regurgitation by itself, as shown by an apical systolic murmur, is the most frequent event at the mitral orifice, though there is doubt as to whether the regurgitation is due to disease of the valve or a dilated mitral ring. A combination of obstruction and regurgitation comes next in frequency, and pure obstruction is least frequent. However, the majority of cases of mitral disease of whatever kind coming to autopsy are found to have stenosis. This is due to the fact that stenosis is the natural result of prolonged inflammation of the mitral valve. At the aortic orifice, regurgitation is very much commoner than obstruction. In rheumatic cases aortic disease is commonly associated with mitral disease. A higher proportion of the cases following scarlet fever have aortic disease than of those that follow acute rheumatism. Pure aortic disease is due to syphilis, and not commonly to acute rheumatism. On the right side of the heart the tricuspid regurgitation that is quite commonly met with is due to dilatation of the muscular ring secondary to left-sided failure, and so is not really a valvular lesion at all.

Compensatory dilatation and hypertrophy affect primarily the particular chamber of the heart with which the affected valves are in relation. However, when failure of compensation occurs the other chambers of the heart become involved. For instance, if the left ventricle dilates, the muscular ring from which the mitral valve is suspended shares in the dilatation. This causes mitral regurgitation. This leads to engorgement of the left auricle and of the lungs with rise of the pulmonary blood pressure. To overcome this resistance the right ventricle hypertrophies. If dilatation of this chamber occurs, it leads to tricuspid regurgitation with engorgement of the abdominal viscera. Valvular disease is often associated with fatty and fibroid degeneration of the myocardium. This degeneration may be due to the same cause as produced the original valvular disease, *e.g.* rheumatic fever, syphilis, etc., or it may be the direct result of lack of nutrition of the heart muscle. There is a tendency at the present day to consider the state of the myocardium as the all-important factor in determining the onset of cardiac failure in valvular disease, and it is probably correct that although valvular disease unaccompanied by myocardial changes may cause symptoms of breathlessness and exhaustion after exercise, indicating relative failure of compensation, complete failure of compensation will be hardly likely to occur if the condition of the myocardium is sound. At the same time the heart should be regarded as a whole. It is really impossible to separate the effect of valvular disease from that of myocardial changes, if both are present together.

AORTIC DISEASE

There are two main causes of aortic valve disease. In the first place, there is acute rheumatism. Here disease of the aortic valves was in 62 per cent. of cases associated with disease of the mitral valves ; in 38 per cent. the aortic valves were affected alone. In the second place, there is syphilis. This disease usually produces primarily an aortitis, and the aortic valves become involved in the same process, while the mitral valves are usually not affected. In a series of 296 cases of aortic disease acute rheumatism was responsible for 67.5 per cent., with men and women in about equal proportion. Syphilis (three men to one woman) for 18.6, atheroma (nearly all elderly men) for 6.8, other causes for 7.1 per cent.

Morbid Anatomy. The changes in the aortic valves consist in thickening

towards the base of the cusps with fibrous tissue, and to a less extent of the free edge, with shortening of the radial measurements, so that the cusps cannot meet to cover the orifice. See also Hypertrophy of the Heart.

Since the three cusps are discrete, chronic inflammation usually causes them to shrink independently of one another, so that there is aortic regurgitation with thickening of the endocardium owing to friction by the regurgitant stream. There may be some thickening at the three points on the wall of the aorta where the valve segments meet, and they are commonly slightly adherent at these points, but not enough to cause stenosis of the opening. It is rather uncommon for the valves to be so fused together or thickened from calcified or bony deposits so as to present an obstruction to the flow of blood—a great contrast to the case of the mitral valve. But, when there is stenosis, there is also usually some regurgitation as well. Exceptionally the fusion is so complete as to allow only a small opening for the passage of blood into the aorta, and yet the valve closes well. The lesions may be aggravated by frequent and continued strains upon the circulation, especially from the excessive use of the arms, such as arises in blacksmiths, sawyers, and others with laborious occupations. Sudden rupture of a valve also sometimes takes place, when it has been softened by inflammation.

AORTIC STENOSIS

Pathology. In Cohnheim's classical experiments on animals a ligature was passed round the aorta and gradually tightened. The lesion was compensated for by the greater power of the muscular contractions of the ventricle, *i.e.* the output of the heart per minute, and the arterial and venous pressures remained the same, but the intra-ventricular pressure was much increased, the heart rate was slowed, while the actual duration of the contraction of the ventricle was increased in the endeavour of the heart to force its content of blood into the aorta against this artificially increased resistance. It was only when the constriction reached a certain limit that the heart suddenly failed.

Exactly the same conditions are present in aortic stenosis caused by disease, except that here, since the lesion has been produced gradually, the heart has had time to adapt itself. The increased work that falls on the heart causes a primary hypertrophy of the left ventricle. With a stationary lesion this is sufficient by itself to empty the ventricle completely through the narrow opening at each systole. Only when compensation begins to fail is there a dilatation of the ventricle, which spreads to the other chambers of the heart.

Symptoms. In pure *aortic stenosis*, which is an exceptional condition for reasons already explained, the murmur is systolic, audible in the second right intercostal space near the sternum, traceable up towards the right clavicle, and audible in the carotid arteries, and it is usually accompanied by a rough systolic thrill felt at the same spot. The pulse is often characteristic; the obstacle interposed in the current of blood prevents the full effect of the ventricular contraction upon the column of blood in the systemic arteries, and the pulse can be felt to have lost its suddenness and to rise quite slowly. The pulse tracing is then *anacrotic*, that is, the percussion wave is lower than the succeeding tidal wave, and appears as an elevation on the ascending limb. In the extreme variety of this form this wave is rounded off, or entirely absent, and the tracing resembles that shown in Fig. 41, A (p 308). The pulse is infrequent and sluggish when palpated (*pulsus tardus*). When the aortic stenosis is fully compensated the patient may have no symptoms. In other cases pain in the chest and a feeling of oppression may be noticed. When compensation begins to fail, shortness of breath and signs of venous congestion will be observed.

AORTIC REGURGITATION

Pathology. If one of the aortic valves is experimentally damaged in an animal, compensation takes place at once, just as in aortic stenosis. The output

is regurgitation. But there is also shortening of the valve circumferentially, leading to stenosis, and the longer the inflammation lasts the greater the stenosis. These two types of shortening often co-exist, producing a double lesion. Slight inflammation will not cause enough circumferential shortening to cause clinical stenosis, though there may be regurgitation. Severe inflammation may lead to regurgitation alone, stenosis alone, or more commonly to the two combined. The presence of stenosis always means a severe infection of the valve. Post-mortem examination also shows that in mitral disease the cordæ tendineæ are thickened and shortened—so shortened, indeed, that the valve curtain is continuous with the muscoli papillares, and these themselves are invaded by the fibrotic change. In some cases of stenosis there is circumferential shortening without much shortening from above downwards; in other cases both types of shortening exist, so that only a narrow slit presents itself on the auricular side in the dense surface of the valve. A distinction is thus drawn between *funnel-shaped* and *buttonhole* orifices; and the former appears to be very much more frequent in children (8 to 1, Allbutt), the latter in adults (25 to 1).

Mitral stenosis is to be regarded as the final result of chronic infection or of repeated attacks of acute infection on the valve, which lead to adhesion and shrinking and thickening of the cusps. It requires some years for its development. This explains the fact that it is not often met with in children, though it is met with from puberty onwards. Mitral regurgitation, on the other hand, is a less severe form of valvular inflammation, also due to rheumatism.

Symptoms and Physical Signs. There are certain general symptoms and signs, largely due to venous congestion, which are common to both mitral regurgitation and stenosis, and these will be considered here. The early symptoms are noticed particularly after exercise. They are shortness of breath and a feeling of exhaustion; to these may be added pain over the heart, palpitation and swelling of the feet; and this earlier stage may last for several years. The transition to a later stage is often coincident with the occurrence of one of the previously described forms of irregularity of the heart's action, such as premature beats, and especially auricular fibrillation, when the pulse which was previously regular, though rather frequent, becomes grossly irregular both in rhythm and force. When the later stage is reached, the symptoms are in great part the result of the circulatory disturbances, and of the *retardation* of the blood flow, the effects of which upon the organs of the body have been described (*see* p. 252). Thus, as a result of the passive congestion of the lungs the patient suffers from cough, from mucous expectoration, from occasional hæmoptysis, which may arise from the pulmonary infarcts above described, from orthopnœa at night or continually, and from dyspnœa on the slightest exertion. On examination the right auricle will be found to be dilated, with impairment of note and pulsation for an inch or more to the right of the sternum; the second sound in the pulmonary area will be accentuated, while epigastric pulsation will indicate hypertrophy of the right ventricle. Crepitations will be heard at the bases of the lungs, and in advanced cases there will be dulness, with deficient vesicular murmur, and deficient tactile vibration. General venous stagnation is shown by a rich red colour or actual cyanosis of the lips, cheeks, ears, and extremities, by the filling and pulsation of the large veins in the neck, and by the occurrence of anasarca. The congested liver is large and smooth, reaching perhaps to the level of the umbilicus, and it is tender if the congestion has been acute, and it may pulsate; the skin is slightly jaundiced, the yellow tinge of the forehead combining with the deep red of the lips and cheeks to give a very characteristic appearance to the sufferer. There will be dyspeptic symptoms. The secretion of the kidneys is also affected, the urine being scanty, reduced perhaps to 10 or 15 ounces daily, high-coloured, depositing large amounts of urates and containing albumin and fibrinous casts; the quantity of albumin is generally small, and varies inversely as the efficiency of the heart. Drowsiness or restlessness, and in advanced cases occasionally delirium, show the

effect upon the circulation of the brain. Death takes place ultimately from cardiac failure, from œdema of the lungs and exhaustion, or from malignant endocarditis, or other complication (*see also* p. 275).

MITRAL REGURGITATION

Pathology. Since at each systole blood passes back into the left auricle, compensation for this lesion consists in a primary dilatation of the left ventricle and left auricle for the following reason. During systole the auricle receives blood that has leaked back through the mitral valve, but it also receives its normal quota from the lungs, so that it must dilate. All this blood passes into the ventricle, which must also dilate to receive it. The extra work involved in filling up the auricle and ventricle falls to a large extent on the right ventricle, which, in consequence, undergoes secondary hypertrophy, so as to hold more blood, and enable the full quota to be delivered to the aorta at each beat. Hypertrophy of the left ventricle will not be so obvious as in aortic regurgitation, because no work will be done in respect of the blood that regurgitates through into the auricle, since in the latter the pressure is low.

Physical Signs. These are displacement of the impulse outwards, the blowing systolic murmur heard loudest at the apex, which has already been described.

MITRAL STENOSIS

Pathology. In pure mitral stenosis, the primary effect on the heart is hypertrophy of the left auricle, but later on this leads to dilatation as well, especially when there is incipient heart failure. The right ventricle hypertrophies so as to cause a rise of blood pressure in the pulmonary system which acts against the resistance of the narrowed valve. As compensation begins to fail, not only is there congestion in the lungs, but the left ventricle receives less than the normal quantity of blood. The cavity becomes smaller, and the ventricle wall may actually atrophy to some extent, and the aorta become narrower than usual in long-standing cases. Most cases of mitral stenosis are associated with some degree of mitral regurgitation.

Physical Signs. The murmurs of mitral stenosis and their mode of production have been described (*see* p. 221). They are often localised to the apex and are commonly accompanied by a thrill (*see* p. 217). The variation of the murmurs may be summed up as follows: When the heart is beating slowly and the stenosis is slight, an auriculo-systolic murmur is heard due to the hypertrophied auricle. If fibrillation supervenes, the murmur disappears entirely. If the action is slow, but the stenosis greater, murmurs are heard all through diastole; they consist of mid-diastolic and auriculo-systolic murmurs. Sometimes the mid-diastolic and auriculo-systolic murmurs alternate frequently in the same case; either may be replaced by what is apparently a reduplicated second sound audible at the apex (*see* p. 218). In the case of auricular fibrillation, the murmurs occupy the earlier parts of diastole when the pause between the beats is long, or occupy the full diastolic interval when the latter is short. When the heart's action is quick both with normal rhythm and in auricular fibrillation, the murmurs tend to occupy the whole diastolic interval, but it is often very difficult to hear them at all. There may only be an accentuated first sound, and the second sound may be inaudible at the apex.

In early stages the heart is not enlarged; but in later stages general cardiac enlargement takes place when either tricuspid or mitral regurgitation supervenes.

Symptoms. Mitral stenosis often gives rise to hæmoptysis quite early owing to congestion of the lungs, and also to attacks of giddiness and faintness due to cerebral anæmia, and is more often than mitral regurgitation the cause of hemiplegia from embolism of the cerebral arteries. This arises from thrombi in the

left auricle, which are formed owing to the stagnation of blood in the later stages of the disease. The other general symptoms have been described.

RIGHT-SIDED VALVULAR DISEASE

Tricuspid Regurgitation. Though tricuspid incompetence is a very common condition, it is usually due to the dilatation of the right ventricle, which is associated with mitral disease, pulmonary stenosis, myocardial disease, or with other conditions causing obstruction in the lungs (emphysema, bronchitis, asthma, fibroid phthisis). Much more rarely is it due to organic disease, similar to that which attacks the mitral valve. It is commonly accompanied by the evidence of dilatation of the right auricle, and by the various degrees of œdema, anasarca, and venous congestion which indicate a difficulty in the return of blood to the right heart and lungs. These have already been enumerated under the later symptoms of mitral disease. The murmur of tricuspid regurgitation has been already described (*see p. 222*) ; it is sometimes accompanied by a systolic thrill over the lower end of the sternum. The pulsation of the internal jugular vein, which occurs in these circumstances, may be very pronounced, causing an extensive undulating movement of elevation and subsidence at the side of the neck between the ear and the clavicle posterior to the course of the carotid artery. The external jugular vein may pulsate at the same time. The force of the right ventricular contraction may also be transmitted to the hepatic veins, so as to cause *hepatic venous pulse*, or *pulsating liver*. The organ is commonly much enlarged, and can be felt throbbing over its whole surface ; and the pulsation is sometimes even conveyed behind into the right loin under the last rib, so that the liver can be felt to expand between the hands placed in front and behind.

Tricuspid stenosis is less common, and is generally observed in conjunction with disease of some other valve, especially mitral stenosis. No special group of symptoms can be referred to it apart from those seen in tricuspid regurgitation.

Disease of the pulmonary valves is mostly congenital if of old standing, and if acute it is the result of malignant endocarditis. *Pulmonary stenosis* combined with deficiency of the intra-ventricular septum is the usual condition in the former case, and is described later. (*See Congenital Malformations.*)

Pulmonary regurgitation sometimes occurs as a result of mitral stenosis, the valves yielding before the great pressure in the pulmonary artery ; a diastolic murmur is heard along the left side of the sternum.

Malignant endocarditis may cause a double (systolic and diastolic) murmur at the pulmonary orifice like that of aortic disease, the respective murmurs having the positions previously noted. The symptoms under such conditions have already been detailed (*see Malignant Endocarditis*).

DIAGNOSIS, PROGNOSIS, AND PREVENTION OF CHRONIC VALVULAR DISEASE

Diagnosis. In the diagnosis of valvular heart disease many questions have to be considered. It has to be determined (1) whether a murmur is due to a valvular lesion or to some other cause, endocardial or exocardial, the former including change in the muscular walls ; (2) at which orifice it arises, and if there are two, whether one is dependent on the other ; and (3) what is the functional capacity of the heart, *i.e.* its response to exercise and the condition of the several cavities of the heart. Very important information as to the heart's position, action, and valvular working can be got by the eye and the hand ; and these should always be used in conjunction with the stethoscope. The Röntgen rays will also assist in the estimation of changes in the size and shape of the heart's cavities (*see Fig. 12, p. 225*).

1. The murmurs of valve disease are apt to be confounded with those due to

other conditions. *Anæmia* produces a harsh systolic murmur over the pulmonary area. Seeing the rarity of organic pulmonary disease, this is mostly distinctive enough, but with very considerable anæmia murmurs extend over the whole præcordial area, arising, no doubt, at other orifices besides the pulmonary. As in such cases the patients are short of breath, with a tendency to palpitation and to swelling of the feet, the diagnosis may be difficult. The marked pallor of the anæmic cases, the absence of history of rheumatism or other precursor of heart disease, and the diminution of the murmur under the use of iron tonics, are points which will help. But anæmia may also undoubtedly itself be a cause of mitral regurgitation; the deficient quality of the blood causes malnutrition of the wall of the ventricle; this dilates, the mitral orifice yields, and regurgitation is the result. This is, indeed, an actual lesion, and the murmur is immediately due to structural changes in the orifice, if not in the valve itself; but inasmuch as they are primarily due to a condition of the blood which, together with its results, is curable, this murmur is often spoken of as *functional* or as *hæmic*. The diagnosis must, at any rate, be made between this and chronic valvular disease, and it can generally be effected by a consideration of the preceding and associated circumstances—viz. the absence of rheumatism and the decided anæmia.

Aneurysm of the aorta frequently gives rise to a murmur at the base of the heart which may be mistaken for that of aortic obstruction. Indeed, a simple systolic murmur in the aortic area, unaccompanied by regurgitant murmurs, is much more often due to aneurysm than to stenosis of the valves. Abnormal pulsation to the right of the sternum and increased area of dulness should be sought for as further evidence. If the murmur is localised at a point not strictly corresponding to the known areas of valve disease, aneurysm is still more probable.

Pericarditis often gives rise to a to-and-fro sound, very like the murmur of double aortic disease. It is, however, usually rougher, less uniform in loudness over a large area, not strictly localised to the usual area of aortic disease, and perhaps here and there not strictly synchronous with the two periods of the heart's beat. A short history of acute illness, unusual pain, or distress at the heart, increased area of præcordial dulness in an upward direction, and absence of splashing pulse, point to pericarditis.

Another difficulty arises from *exocardial* murmurs, which are sounds synchronous with the heart's action, but produced outside the heart. But the recognition that a murmur is endocardial and produced at a valvular orifice does not carry with it the diagnosis of disease of the valve. Ventricular dilatation not only from anæmia, but from any cause whatever, may lead to an apex systolic murmur; and such an occurrence is most common in Bright's disease, in alcoholism, and in arteriosclerosis, and acutely in the myocardial disorders of infectious disease.

Chronic renal disease may bring about hypertrophy of the heart, and even dilatation and murmur; and the case will then closely resemble one of mitral disease with secondary albuminuria. The difficulty is increased by the fact that the kidneys in a state of chronic congestion from heart disease may become granular; and that a heart dilated, as a result of extreme arterial tension in renal disease, will cause secondary stagnation in the venous system, like one affected with primary mitral disease. In primary heart disease one must look for the history of rheumatism or other cause of endocarditis. The urine has the characters described (*see* p. 271), and the pulse is small and of low tension. But in renal disease the urine is more likely to be pale, though also scanty, and to have a more uniform quantity of albumin; and the pulse is one of high tension. In enlargements due to arteriosclerosis and to alcohol, conditions which are often combined, the arterial tension is variable, and albumin is often absent; the diagnosis may have to depend on the history or associated conditions.

Conversely a valvular lesion is sometimes present when no murmur can be heard ; this is most frequently the case in the later stages of mitral constriction, when the strength of the auricle is failing.

2. The diagnosis of the different forms of valvular disease one from another depends for the most part on the character of the murmurs, and the extent to which they are audible over the præcordial area. A murmur may be conveyed beyond the area of one valve into the area of another, when it will be necessary to compare carefully the intensity of the sound at different points. Aortic regurgitation and mitral regurgitation are nearly always indicated by their characteristic murmurs. Mitral obstruction frequently exists without its characteristic murmur, as above stated. Pre-systolic murmurs and diastolic murmurs, when heard at the exact impulse (and not heard at the base), are very strong evidence of mitral obstruction. But murmurs identical with these are sometimes heard at the apex in association with aortic regurgitation—Flint's murmurs (*see* p. 269)—with adherent pericardium, and with a dilated ventricle under other conditions. The explanations of these anomalies are various : vibrations of the anterior mitral cusp from impaction upon it of the aortic regurgitant current, or from its being driven in upon the auriculo-ventricular current ; mingling of the above two currents ; the formation of a " fluid vein " in consequence of the dilatation of the left ventricle, while the mitral orifice is of normal size, a condition sometimes called relative stenosis. The last is the more likely explanation.

3. The estimation of the heart's response to exercise is perhaps the most important point in diagnosis. The amount of breathlessness or exhaustion after exercise is observed (*see* p. 223). The size of the heart provides a useful guide as to the extent of the valvular defect. This may be determined by palpation and percussion. X-rays may be used, and also the electro-cardiograph to indicate the proportion of right- and left-sided hypertrophy (*see* p. 249).

No diagnosis can be made without an examination of the heart and lungs ; but it is interesting to note that there is often in children and young people a superficial resemblance between mitral disease and phthisis, since the former may produce marked pallor, emaciation, and hæmoptysis.

Prognosis. A study of 1,000 cases of heart disease in ex-service men reviewed after ten years (20) showed that the most important elements for a bad prognosis are a poor exercise tolerance and a large heart. Thus with moderate enlargement and poor tolerance about half the cases die within ten years, a few survive unchanged ; while with great enlargement 76 per cent. and congestive failure 97 per cent. die within ten years, 80 per cent. being the rate of survival of these two grouped together.

Of the whole series, 22 per cent. have lived uneventfully and unchanged through the ten years, and this figure is probably on the low side. Half the cases have died, mostly of congestive failure, and this failure was associated with infective endocarditis in 26 per cent. of failure cases and with auricular fibrillation (30 per cent.), while bronchitis and other infections were also noted. Sudden death accounted for 17 per cent. of all the deaths.

When the cases are grouped according to auscultatory signs, 35 per cent. of those without obvious valvular disease die within ten years ; the death rate of aortic stenosis and syphilitic aortic regurgitation is 60 per cent. (or 58 per cent. excluding aneurysm) ; the death rate of uncomplicated non-syphilitic aortic regurgitation is 33 per cent., of combined regurgitation and mitral stenosis 30 per cent., of mitral stenosis 37 per cent. (excluding fibrillation 29 per cent.) ; with early mitral stenosis the death rate is 10 per cent., with developed stenosis 39 per cent., with slight aortic regurgitation 16 per cent., with free regurgitation 45 per cent. Hence the nature of the valvular lesion is less important than modifying factors. There are two factors, dealt with elsewhere, which are of special importance in prognosis—auricular fibrillation and subacute bacterial endocarditis, *q.v.*

Although this series of cases excludes children and women, it is of special value because it comprises, so to speak, a whole section through a diseased population—ambulant as well as bedridden ; in the last edition it was necessary to be content with an analysis of patients who had died in hospital ; this is now replaced by more complete statistics. Some points may be specially emphasised—the unimportance of a mitral systolic murmur. In the case of soliders invalided with the effort syndrome the presence of a mitral regurgitant murmur was of no value as an indication whether the man would be able to return to full duty or not. Mitral stenosis is a serious lesion, as it is the end result of chronic or repeated acute attacks of rheumatic mitral disease. In slight cases, however, it may remain stationary for years if the infection is arrested. The combination of aortic regurgitation and mitral stenosis does not make the prognosis worse. Repeated attacks of acute rheumatism in childhood or other infections are dangerous, because they may lead to further damage to the myocardium or valves ; the liability to mitral stenosis, and of elderly patients to auricular fibrillation ; the fact that the *immediate* prognosis in congestive failure is improved if there is fibrillation, but the ultimate prognosis is worse ; the liability to sudden death of the aortic group and to bacterial endocarditis in non-syphilitic aortic regurgitation ; the added seriousness of pregnancy.

Prevention. Since most of the cases of heart disease in young children are due to acute rheumatism, prevention consists in counteracting this disease, as already described.

In older subjects the teeth should be examined, particularly in people who already have chronic valvular disease, as any infection they may pick up may lead to infective endocarditis. *Pyorrhœa alveolaris*, when there is a free discharge of pus, is not so dangerous, but care should be taken to exclude abscesses hidden away at the roots of the teeth, from which the pus is not discharged, and which may lead either to an acute attack of endocarditis, or to a chronic smouldering infection with progressive deformity of the valves.

Another very important point in prevention is to ensure that the child who has suffered from the mildest rheumatic manifestations is put to bed whenever there is any indication of acute infection, such as a sore throat, tonsillitis, or a common cold, because there is always the chance that the heart may be simultaneously affected. In fact, it is the greater care taken about children of the better classes in this respect that probably ensures their relative freedom from severe heart disease compared with children of the working classes.

Of the specific infections syphilis is the commonest cause of heart disease, and early intensive anti-syphilitic treatment should be carried out, if the disease is contracted.

Arterial disease leads commonly to myocardial degeneration, and the appropriate prophylaxis (*q.v.*) should be undertaken.

TREATMENT OF CHRONIC CARDIAC DISEASE

The following remarks apply not only to chronic valvular disease of the heart, but also to cases of adherent pericardium and myocardial degeneration.

Before considering treatment it is necessary to find out (1) whether there are early signs of cardiac failure—distress, breathlessness and substernal or præcordial pain after exercise ; (2) whether the later signs are present—engorgement of the veins in the neck and of the liver, cyanosis, and œdema ; (3) whether the heart is enlarged, and whether there are signs of valvular disease or myocardial changes ; (4) whether there is any cardiac irregularity, particularly auricular fibrillation ; (5) whether there is evidence of active infection in the heart (Lewis).

The principles of treatment consist in ordering the life of the patient, so that the work the heart is called upon to do is well within its capacity.

In early cases of cardiac failure the patient's symptoms are the main guide. It is necessary to find out the amount of work that causes the onset of undue

fatigue, or distress, or breathlessness, or of cardiac pain. In the perfectly healthy individual these symptoms are only experienced after the most severe muscular exercise. Recent experience has taught that there are many individuals with systolic murmurs audible over the præcordium who have no history of rheumatic or other infection, and show no enlargement of the heart, who can take the most severe muscular exercise with no more distress than the normal person experiences. Such persons need not be restricted in regard to the exercise they take. When, however, there is reason to suspect aortic regurgitation or mitral stenosis, it is wise not to allow the patient to call forth his whole cardiac reserve, even if violent exercise can be undertaken with no more than the normal amount of distress. Only the milder forms of exercise should be permitted. The same thing applies to cases of mitral regurgitation and aortic stenosis when there is definite cardiac enlargement.

In patients who exhibit symptoms after moderate exercise, such as running or walking upstairs or uphill quickly, or walking quickly along the level, the exercise causing the symptoms should be forbidden. At the same time such exercise as can be tolerated should be allowed. It is bad practice to under-exercise his heart. However, the patient should be told to remain quite still supposing the symptoms come on while out for exercise.

Rest in bed is indicated in all cases where actual infection is present, in all cases of advanced cardiac failure, in cases showing signs of venous congestion, in cases of auricular fibrillation where the heart is rapid, and it is required to administer a full course of digitalis, and, most important of all, in patients who show signs of distress when standing or walking leisurely. The patient should lie recumbent, unless there is orthopnoea, when he should be propped up in bed. Complete quiet and freedom from anxiety and excitement should be enjoyed. All unnecessary movement should be forbidden, and, in particular, sleep should be encouraged, as this is the condition that gives the heart its most complete form of rest. This is one of the most important points to be attended to in the treatment of any cardiac patient, whether some exercise is allowed or not. Nine to ten hours in bed should be aimed at, even though the number of hours of actual sleep is less than this. Whisky, 1—2 ozs., may be given as a soporific, or paraldehyde in doses of 1—2 drachms. The diet should be sufficient, simple, and readily digestible; it may be mixed solid and liquid, in quantity at any one time not to overload the stomach, and of a nature not to cause flatulence or distension. Fluids should not be given in excess and salt intake should be cut down if there is oedema. In obesity a low calorie should be given, since obesity is a common cause of raised metabolism. Heart disease has also recently been treated by thyroidectomy in order to lower the metabolism and diminish strain on the heart.

When a patient has obtained relief after rest in bed for some time, exercise should only be begun gradually. Graduated exercises may be given by allowing him to move his arms and legs while still in bed. Another plan, when the patient is up, is to increase the amount of walking from day to day until his exercise tolerance is reached.

In cases of advanced cardiac failure with congestion of various organs and oedema, there are three main lines for treatment: (1) Removal of oedema fluid or bleeding; (2) administration of oxygen; (3) of drugs, especially digitalis.

(1) If much fluid is present in the pleural cavity, its removal by tapping will bring great relief. If there is much anasarca, the legs may be punctured in ten or twenty places with a large flat surgical needle, or drained by Southey's tubes. The patient should sit upright in a chair for twelve or twenty-four hours with the legs down, so as to allow the fluid to gravitate into them. They must be cleaned scrupulously and painted over with a weak solution of iodine. The fluid is allowed to run down into a bath, which should be surrounded with a blanket for warmth, but the blanket must not touch the legs where they have been

punctured. In ascites the abdomen may be tapped, and by these proceedings the pressure on the circulation is diminished. The indications for *venesection* are severe orthopnœa, and cyanosis with distended veins. This means that there is a fall of general arterial blood pressure and a corresponding rise in venous pressure, so that the right side of the heart has become so engorged that it has difficulty in contracting upon its contents. In such circumstances, auricular fibrillation is often present; the withdrawal of blood to the extent of 20 or 30 ounces by a cut into the median basilic vein relieves the distress by diminishing the blood flow to the heart. A still more rapid effect may be obtained in extreme cases by opening the external jugular vein at the bottom of the neck. In this case the blood will flow from the central end if the venous pressure is high, and the right side of the heart will receive direct relief. It is not always easy to obtain enough blood by a simple cut into the vein. A more effective method is to use a short wide hollow needle connected to a closed bottle by means of rubber tubing. Suction can then be applied to the bottle.

(2) Oxygen should be given in all cases of heart failure with secondary pulmonary complications and in myocardial degeneration, particularly when it is probable that the coronary arteries are sclerosed. It is usually not effective in the heart failure of rheumatic origin in young subjects. Dyspnœa and cyanosis are the best indications, but when in doubt its effect should be tested, using a mask and valves. It may be given by nasal catheter; but a tent is recommended (*see* p. 156).

(3) The *drugs* which act directly upon the heart in a favourable sense are comparatively few. Digitalis is the most valuable and the one whose action has been most studied. In auricular fibrillation its use has already been described (*see* p. 244). In these cases the ventricle is beating rapidly and irregularly, and digitalis acts like a specific. The pulse is slowed. The urine is increased in volume, and the œdema disappears. But in other cases, even when auricular fibrillation is not present, digitalis may be used with success, especially for its diuretic action. The powdered leaves are often combined with mercury in the form of a pill which is used for such cases. It cannot be said that its action is so certain as in auricular fibrillation. Digitalis may be given by mouth in powder, infusion, or tinctures or as one of its active principles, digitalin or digitoxin. In serious cases 2 drachms of the infusion or 10 or 15 minims of the tincture may be given every three or four hours at first, and after twelve or twenty-four hours less frequently or in smaller doses. The dose of digitoxin is $\frac{1}{2}$ to $\frac{1}{4}$ grain. Given in these doses, digitalis takes two or three days to produce its full effect. Much more rapid action is obtained by giving massive doses by mouth, a treatment that may be carried out when there is auricular fibrillation. Toxic symptoms arising during digitalis treatment are described on p. 245.

Some other drugs have an action like that of digitalis. The most important of these is strophanthus (dose, 2 to 5 minims of the tincture). The active principle of strophanthus, strophanthin, is valuable where there is no time to be lost in cases of serious failure. $\frac{1}{2}$ to $\frac{1}{4}$ grain may be given intravenously. It may also be injected intramuscularly or subcutaneously. The treatment of auricular fibrillation by quinidine has already been described (*see* p. 246). Strychnine has been regarded in the past as a valuable cardiac tonic. A carefully controlled series of observations has shown that strychnine has no effect either in acute or chronic cardiac failure (21). Oubaine ($\frac{1}{4}$ mg. intravenously, or 1 mg. by mouth, once or twice a day) has been recently used for myocardial degeneration in France, to increase the tonicity of the left side of the heart.

Other symptoms and complications may have to be treated. If dropsy does not yield to digitalis, *theobromine sodium salicylate* (diuretin), in doses of 10–20 gr. t.d.s., is the best drug of the purin series to use, either in the form of tablets or in a mixture well flavoured with syrup of ginger. These drugs probably act by increasing the permeability of the glomerular membrane or perhaps increasing

the number of active glomeruli. They do not involve an increased oxygen consumption by the kidney ; but they may obviously be ineffective if the glomerular capillaries are engorged and perhaps suffering from anoxhæmia. *Urea* may also be tried in doses of 5–15 grams. *Urea* filters through the glomeruli ; and is also excreted by the tubules, so that the osmotic pressure of the tubal fluid remains high and less water is reabsorbed by the tubules lower down and so is excreted. Finally, *salyrgan*, an organic mercury compound (up to 2 c.c. intramuscularly) and *neptal* (up to 1 c.c.) once or twice a week are much more effective diuretics than the old-established *Pil Hydrarg.* They are still more effective when combined with the oral administration of ammonium chloride in doses up to 100 grains in the twenty-four hours. The latter acts by producing an artificial acidæmia so that the colloids give up some adsorbed fluid, and this fact must be remembered when there is some associated nephritis, where acidæmia may be present already. Pain over the heart is often severe, and may be relieved by belladonna plasters, by small doses of morphia internally, or by subcutaneous injection of gr. $\frac{1}{4}$. Cough may be treated with small doses of expectorants and sedatives (*see Treatment of Bronchitis*), and vomiting by effervescing salines. In aortic disease with hypertrophy, one of the most distressing symptoms is the violent action of the heart and the throbbing of the great vessels in the neck and over the body generally : and this may be much relieved by the use of a small dose of tincture of aconite (1 to 3 minims), by bromides, or by a small dose of morphia. Pulmonary hæmorrhage is rarely sufficient to threaten life, and does not require styptics. In cases of sudden arrest or weakening of the heart's action, especially during anæsthesia, when death is imminent, life may be restored by injecting 1–3 c.c. of 1 in 1,000 adrenalin into the right ventricle from a syringe. The needle, 3 inches long, is passed directly backward above the fifth costal cartilage, close to the left side of the sternum, slightly inwards. Its arrival in the ventricle at a depth of $1\frac{1}{2}$ to 2 inches is indicated by withdrawing a little blood before making the injection.

In myocardial disease of elderly subjects and often in aortic disease, paroxysmal attacks of breathlessness cause much distress. Oxygen provides relief, and is preferable to repeated subcutaneous injections of morphia, which also give relief (25). On the view that the breathlessness is due to incipient pulmonary œdema from relative left-sided failure (*see p. 252*), the author has used with success Plesch's method of raising the pressure of air in the lungs as described under pulmonary œdema.

Syphilitic myocarditis should be treated over an extended period with anti-syphilitic remedies. Deep subcutaneous injections of sulfarsenol (0.3 to 0.48 gram) may be given weekly. A course consists of 6 grams, and six weeks are allowed to elapse between the courses. During the course yellow iodide of mercury, gr. $\frac{1}{8}$, may be given three times a day as tabloids, and increased to 8 or 12 a day. Potassium iodide may be given between the courses.

Heart Disease and Pregnancy. The question not uncommonly arises as to whether pregnancy should be allowed in patients who on auscultation are found to have murmurs characteristic of mitral regurgitation, mitral stenosis or aortic regurgitation. Pregnancy should be permitted : (1) if there is evidence that the valvular defect is of long standing and that there has not recently been any inflammation in the valves ; (2) if the response to effort is good ; (3) if the heart is not enlarged or unduly excitable ; (4) if the rhythm is normal ; (5) if in aortic regurgitation there is no great difference between the systolic and diastolic blood pressure, and the apex beat is not too far out or too forcible ; (6) if in mitral stenosis no persistent crepitations are heard in the lungs after coughing or deep breathing, indicating commencing œdema. No attention should be paid to the occurrence of extra systoles in pregnancy ; but the presence of auricular fibrillation should be looked upon as an absolute bar (Mackenzie). If pregnancy has been begun against advice the case must be carefully watched and pregnancy

terminated if unfavourable symptoms present themselves. When the heart shows some signs of functional inefficiency the patient should rest, propped up in bed, taking deep breaths at intervals during the day so as to aid the circulation through the lungs. Induction of labour during the later months of pregnancy is often a long business, and so is more of a strain on the heart than if labour comes on spontaneously. In such a case Cæsarean section may be considered, especially as sterilisation by resection of parts of the Fallopian tubes can be performed at the same time. Mackenzie states that no degree of heart disease in a married woman is a bar to sexual connection, supposing she feels the desire for it, and ability to perform it.

MALIGNANT ENDOCARDITIS

(*Infective, Septic, Ulcerative or Bacterial Endocarditis*)

Ætiology. Acute rheumatism is an antecedent of malignant endocarditis, but the proportion of cases (fifty-three out of 160—Osler) is less than that in which rheumatism is related to simple endocarditis; in some of these the symptoms have developed in the course of the rheumatic fever, and in others they have arisen in the stage of chronic valvular disease, which predisposes to the occurrence of infection. On the other hand, malignant endocarditis may occur even though the valves are healthy, especially after exposure and hard muscular work. This has been verified by war experience (19). Besides rheumatism, its predisposing cause may be found in acute pneumonia, in the eruptive fevers such as scarlatina, in puerperal processes, in the existence of open wounds on the surface of the body, in septicæmia and pyæmia. Purulent discharges from the mucous membranes (urethritis, vaginitis, pyorrhœa alveolaris) may give rise to the disease, but the latter is more likely to arise when for some reason the pus is held back, and there is no free drainage. This is particularly likely to occur in the chronic tonsillitis of children, or dental abscesses in the case of adults. Of 1,000 ex-servicemen with cardiac disease subacute bacterial endocarditis attacked 12 per cent.; it was responsible for death in 32 per cent. of non-syphilitic aortic regurgitation cases, but in only 6 per cent. of mitral stenosis (20).

Various micro-organisms are found in the organs in infective endocarditis. Streptococci, *i.e.* *S. viridans*, similar to those found in the mouth or large intestine, are most common; staphylococci, meningococci, pneumococci, the *Bacillus pneumoniae* of Friedländer and the bacilli of tubercle, diphtheria, and typhoid and the gonococcus and anaerobic bacilli are found occasionally. From some centre of infection the organisms find an entrance into the blood and are thence deposited on the valves. Streptococci are often found in the blood during life in the acuter forms of the disease.

Morbid Anatomy. In this form of endocarditis the tissue of the inflamed valve is softened, and breaks down, so that erosions or ulcerations take place, and, as a result of this, fibrin is deposited upon the roughened surface, and accumulates into irregular masses of vegetations, which may reach the size of a hazel nut. By suitable methods the micro-organisms can be demonstrated on the surface, and more or less deeply in the substance of the vegetations, where they form considerable masses in acute cases, while beneath the infected surface there is a zone of polymorphonuclear infiltration; when the disease is chronic the micro-organisms are far fewer and processes of repair by means of fibro-blasts are more obvious. Several important changes result from these processes in the valve. The valve itself may be perforated, or strips of tissue may be partly separated and hang loosely in the blood current, or portions may be completely detached. Sometimes a part of the valve is so weakened by the destructive process that it yields before the pressure of the blood, and a saccular dilatation, or *aneurysm*, of the valve is formed, projecting on the opposite side. Another result is the occurrence of endocarditis, or endarteritis, in adjacent parts from a strip of the valve playing backwards and forwards

in the blood currents with the systole and diastole of the ventricle, and striking alternately the walls of the cavities in front and behind. At the spot struck infection takes place, and causes a fresh patch of inflammation of the lining membrane.

But the most important effect of malignant endocarditis is the infection of the whole arterial system by particles detached from the valves being carried to remote parts ; and it is to this process, combined with the presence of organisms in the detached fragments, that the special features of this disease are due. Embolism may take place in almost any part of the body. It is especially common in the vessels of the spleen and kidneys, but it happens also in the vessels of the brain, alimentary canal, skin, retina, and lungs, and the larger arteries supplying the limbs, such as the radial, ulnar, tibial, brachial, and others. The local results of these impactions are : (1) Obstruction of the circulation ; (2) necrosis or hæmorrhage, or both, within the area of distribution of the obstructed vessel, and the formation of infarcts ; and (3) suppuration in the same area from the septic influence of the micro-organisms, when the process is acute (*see* Embolism).

The effects upon the various organs, as they may be seen in different cases of malignant endocarditis, are—softening and abscess of the brain, and meningitis ; retinal hæmorrhages and optic neuritis ; diffused swelling, infarction, and abscess of the spleen. There are three ways in which the kidneys may be affected : (1) there may be acute toxic nephritis ; (2) there may be an acute focal embolic nephritis giving rise to *flea-bitten kidneys*, which are often large and speckled with hæmorrhagic points upon a white ground. Microscopically there are intracapsular hæmorrhages of varying size which gradually become organised and a patchy œdema of the interstitial tissue, without lipoid ; (3) by infarction. There may also be hæmorrhages under the skin, hæmorrhagic infarctions and abscesses of the lungs, pleurisy and empyema.

Malignant endocarditis, like simple endocarditis, affects chiefly the left side of the heart ; but the proportion of cases in which the right side is involved is much larger than in the simple form. In the majority of cases malignant endocarditis occurs on valves showing the effects of previous simple endocarditis.

Symptoms. The symptoms and course of the disease present the greatest variety. In some cases the symptoms at first are simply the occurrence of fever with afternoon rises of temperature, or perhaps sweating, in a patient living an active life, though perhaps known to have valvular disease, more or less perfectly compensated. The temperature may be high, reaching 102° or 103° ; but it is generally remittent or intermittent, and sometimes with remarkable regularity for long periods. There is often free perspiration, and there may be an occasional rigor. The pulse is rapid, ranging from ninety to 120, or even higher. If the heart be auscultated, a murmur will generally be heard at one or other orifice, mostly, however, on the left side. Still it must not be forgotten that in these cases murmurs may be entirely absent. The spleen is commonly enlarged and albuminuria and hæmaturia may be present, and there is a secondary anæmia. The case occasionally resembles an acute nephritis. Where there is a previous history of rheumatism, or known cardiac disease, there may be abnormalities in the size and action of the heart.

In a considerable number of cases there is a close resemblance to *typhoid fever*, chiefly on account of the almost spontaneous occurrence of fever, with headache and enlarged spleen, either from the general infection or from embolism ; but there are no rose spots. Thus, the patient may have been perfectly well until he complains of some such symptoms as usher in other severe febrile diseases, pain in the head, or in the back and limbs, or a definite rigor or rigors. Then follow severe pyrexia, with its usual conditions—high temperature, quick pulse and respiration, dry tongue, loss of appetite, thirst and malaise. Frequently, within a few days, the patient is prostrate, apathetic, drowsy, and at night

delirious ; but the time of appearance of this symptom, determined presumably by the virulence of the toxin, is variable. The condition of the bowels varies, but there are often loose yellow motions, with much resemblance to those of typhoid fever ; and the abdomen may be distended. The duration of these cases is generally from ten days to two or three weeks, that is, much less than in cases of subacute infective endocarditis.

In another group of cases rigors are a prominent symptom, occurring once, twice, or more times in the day, and the resemblance to *pyæmia* from wounds is very close ; in fact, in a case of osteomyelitis, for example, due to *Staphylococcus aureus*, the infective endocarditis may cause no characteristic symptoms, and the lesion may be only disclosed at autopsy. In again another group the organisms invade the cerebral meninges, and the symptoms of meningitis form the prominent feature.

In any case of the disease, to the symptoms dependent upon septicæmic infection may be added those due to the obstruction by embolism of arteries or arterioles. Sometimes embolism of a large vessel in the brain will occur, and cause hemiplegia ; if a vessel in the leg or arm is obstructed, there will be loss of the pulse at the wrist or ankle ; but neither gangrene nor coldness need occur, unless a very large vessel is involved. More frequent are embolisms of the small vessels in the viscera ; there is thus often enlargement and tenderness of the spleen, due in part to infarcts, and the spleen may weigh from 20 to 30 ounces. Infarcts also occur in the kidney, accompanied, it may be, with pain, and the appearance of albumin or blood in the urine. In some cases petechial hæmorrhages appear under the skin, the petechiæ being generally small, and situate on the trunk, about the groins and axillæ ; exceptionally a *purpuric* condition may be present for months. Sometimes small painful erythematous swellings appear on the skin, particularly on the flexor surfaces of the fingers, last a few days and disappear again ; or there is deep-seated pain, and a larger tender lump can be felt beneath the skin in the deeper tissues of the limbs or body, lasting a few days. These are known as *Osler's spots*, and are especially diagnostic in the subacute disease. These are presumably embolic events. Hæmorrhages are often seen in the retina, and there may be also hæmoptysis or epistaxis. Some inflammatory conditions are probably also referable to embolic processes, such as the form of nephritis already mentioned (*see* p. 281), though whether as the result of vascular obstruction or of the introduction of micro-organisms may be doubtful ; albuminuria from nephritis or infarct is frequent. Optic neuritis is sometimes present.

There is a particular group of more or less chronic cases known as *subacute bacterial endocarditis* or *endocarditis lenta* (19, 23, 24). The disease arises insidiously. The patient becomes progressively pale and anæmic, suffers from lassitude, and there are often slight rises of temperature, often not above 100° F. Clubbing of the fingers is characteristic, and there is enlargement of the spleen. Petechial and other embolic symptoms are found occasionally, *e.g.* there may be slight albuminuria, and centrifugalisation of the urine may disclose the presence of blood cells. Osler's spots are specially characteristic of this form of the disease.

The duration of malignant endocarditis is very variable. Some cases last six or seven months with little else than a constant pyrexia ; cases of a pyæmic or severe typhoid type, and those with meningitis, are often fatal in a few weeks or days. Death occurs commonly from cardiac failure or uræmia, or embolism.

Diagnosis. This rests upon the pyrexia of remittent or septic type, the existence of valvular disease, and the evidences of embolism above enumerated ; marked anæmia and optic neuritis, if present, are also valuable signs. But a murmur may be wanting throughout the whole illness ; and even if present the valvular disease does not exclude the possibility of influenza, typhoid, or tuberculosis. Thus the diagnosis may often have to depend upon the occurrence of

symbolisms. Malignant endocarditis is frequently mistaken for *typhoid fever*, and agglutination tests should be carried out. In some of the subacute cases the spleen may be so enlarged, and the anæmia so considerable, that *splenic anæmia* is simulated; this is all the more likely if there are petechiæ or hæmorrhages from the mucous membranes and if the murmur is not unmistakably organic. *Malaria* may also be suggested by septic endocarditis. A continued pyrexia without obvious signs may be due to commencing *miliary tuberculosis* as well as malignant endocarditis; but after a time local signs peculiar to one or the other ought to be observed.

The blood should be examined for streptococci and other organisms.

Prognosis. This is exceedingly bad, and the recovery of a well-marked case of either typhoid or pyæmic form is rare. On the other hand, attacks of subacute bacterial endocarditis have subsided, but they may occur again after a varying interval.

Prevention. Cases have arisen after the removal of septic teeth. The safest way for dealing with multiple extraction is to get the dentist to scale and clean up all the teeth very carefully, repeat this in a week's time, and then some days later to carry out all the required extractions at one time. The danger of removing teeth one or two at a time over a long period is that the wounds are liable to be infected by the septic teeth remaining behind in the mouth.

Treatment can obviously be little more than palliative in the majority of cases. As in pyæmia, if there is any wound or sore, it should be rendered aseptic, and an attempt may be made to influence the disease by frequent doses of quinine (5 grains), sodium sulphocarbolate (10 to 20 grains), or sodium benzoate (20 grains). In a few cases good results have followed the subcutaneous injection of an antistreptococcal serum, or of an autogenous vaccine. But it is sometimes impossible to find any micro-organisms in the blood; and even when they are found, and a vaccine can be prepared, it is with rare exceptions useless. A more promising line of treatment when an organism has been isolated is to inoculate a relative and carry out an immuno-transfusion from the relative to the patient. The general rules for nursing and dieting in febrile states are applicable. Profuse diarrhœa may be checked, if required, by astringents. The delirium is rarely so violent as to require any special treatment. Stimulants are naturally given, as the heart's action early tends to be seriously affected.

EFFORT SYNDROME

(Disordered Action of the Heart, Soldiers' Heart)

During the late war the effects of the war strain upon the heart of the soldier have been constantly the subject of observation and study. Thousands of soldiers were at different times invalided for symptoms suggestive of a weak or diseased heart, and in such cases the nature of the cardiac or other lesion, the best method of treatment, and the prognosis as to the patient's future in relation to military service, whether discharge or return to duty, had to be considered. The subject is dealt with in a report by T. Lewis to the Medical Research Committee (Special Report Series, No. 8, 1918); and in this important report are given the results of the study of 1,000 soldiers returned as sick during training or on active service for actual or supposed defects of the cardio-vascular system.

Ætiology. There is a definite symptom complex, called the "effort syndrome," which occurs under a number of different conditions, such as tuberculosis, exophthalmic goitre, valvular disease of the heart, and in other conditions where there is no obvious lesion in the body. It is this latter type of case that is known as "disordered action of the heart"—a name that is

objected to, because it points solely to the heart, and thus gives a bad impression to the patient. Lewis is inclined to think that the heart action itself is only a subsidiary feature in the disease.

Before study and treatment it is necessary to separate off those other diseases causing the same symptoms. In particular, valvular disease of the heart is held to include cases exhibiting aortic or mitral diastolic and pre-systolic murmurs, but not those with systolic murmurs, whether at the base or apex, owing to the uncertainty of the significance of this type of murmur. Systolic murmurs in soldiers only exceptionally mean valvular disease, and often the amount of damage to the valve is but slight. Further, patients who are invalided on the ground of systolic murmurs alone are found when tested to be fit for active service in nearly all cases.

The malady is found chiefly in men of sedentary occupation, and especially among the more intellectual class of workers. Temperamentally they are unusually sensitive. There is a prevalence of teetotalism among them (53 per cent. in 454 cases). A history of venereal disease is very uncommon; on the other hand, there is often the certainty of self-abuse.

The action of the vagus is probably abnormal, as shown by the variation in the pulse rate during respiration, and occasionally there is profound slowing of the pulse, with fainting fits.

The sympathetic system is more easily stimulated and depressed by adrenalin and apocodeine than normal; this suggests that sympathetic stimulation may account for the cardiac acceleration.

There is no evidence that hyperthyroidism is the cause. Experiments have shown that these patients are just as tolerant to thyroid administration as normal people.

The high incidence of rheumatic histories in the patients (23 per cent.), in spite of the absence of physical signs in the heart, suggests the possibility of early myocardial change as the cause in many cases. However, there is no indication of heart block immediately after exercise, as indicated by the electro-cardiograph, which is usually a valuable sign.

Blood cultures are negative.

It does not seem probable that tobacco smoking is the cause of the condition, though it has been proved that tobacco increases the pulse rate in these cases more than in normal people. In the first place, it is as commonly met with in Sikh soldiers, who do not smoke, as in other Indian troops. Again, the consumption of tobacco is not usually inordinate, and, curiously enough, the heavy smokers return to duty in a higher percentage of cases than the light smokers do, but the non-smokers do best of all. An obvious explanation is that the light smokers are not so much accustomed to tobacco as the heavy smokers. There is no doubt that tobacco smoking aggravates the condition.

It is possible that some toxæmia may be at the bottom of the condition; the symptom complex is very similar to that met with in early tuberculosis, and there is often a history of previous infection. In 50 to 60 per cent. of cases infections are legitimately suspected to have played a large part in the production of the malady.

Symptoms. The "effort syndrome" consists of the following symptoms: *Breathlessness.* This is a constant feature, especially on exertion. A respiration rate of sixty to eighty is by no means uncommon during the waking hours. During sleep the rate is normal, and it is usually not increased when the patient is lying at rest in bed. *Pain.* This occurs in about three-quarters of the cases, and varies in character from uneasiness over the præcordia to pain of anginal distribution; it is especially associated with exercise. *Exhaustion* is an almost constant symptom; it is provoked by sustained effort, and is far in excess of that due to fatigue in healthy men. *Giddiness and Fainting.* Giddiness is almost constant, and is associated with change of posture and with effort. Attacks of

fainting are less common. *Palpitation* is frequent, especially with exercise. It is usually due to rapid and vigorous heart beats, and not often to extra systoles, or other well-defined cardiac irregularity. However, extra systoles do occur, and sinus arrhythmia with respiration is not uncommon. *Headache* is almost constant. *Sweating and coldness of the extremities* is common. The response to pilocarpine is greater than normal. Irritability of temper, sleeplessness, inability to fix attention, shakiness, tremor of the hands, and flushing are common. A disinclination to take alcohol in any form (sometimes for conscientious reasons, but as commonly for reasons of distaste) is to be reckoned as a frequent and remarkable association.

The following are the physical signs :—*Increased heart rate*, especially marked in response to emotions, exercise, or alteration of posture, *i.e.* changing from recumbent to erect position. A notable and widely recognised sign is the slow return of pulse rate after effort. *Blood pressure* is usually normal when the patient is at rest, but there is an exaggerated response to emotion or effort, and high readings are often obtained. *Diffuse apex beat* is common, and this may or may not be associated with increased force of the impulse. It is commonly regarded as a physical sign of dilatation of the heart, but X-ray examination by the orthodiagraph shows that there is no enlargement of the heart, so that the physical sign is untrustworthy, in fact the heart is small (56). The *deep reflexes* are usually exaggerated. The *urine* in 60 per cent. of cases is hyperacid, the quantity being reduced, and the ammonia and amino acids are increased. In 20 per cent. the volume is also reduced, and the urine deposits phosphates. The ammonia is normal in amount, but the amino acids are increased. Speaking of the urine generally, calcium oxalate crystals are often found, and spermatozoa are found in large numbers in the morning urines in 15 per cent. of cases. The *blood* shows a leucocytosis, the average being 12,100 c.m., the lymphocytes being increased. A much larger leucocytosis than normal is observed after exercise, the lymphocytes being increased, and the severity of the symptoms runs parallel with the leucocytosis. The electro-cardiograms show no abnormality.

Prognosis. The following criteria decide whether the patient will in future only be fit for sedentary work : a history of rheumatic fever, persistently severe breathlessness on exertion, præcordial pain sufficiently severe to prevent exercise, a pulse rate of 120 and more even in recumbency, symptoms which have been present for many years, even though of only moderate severity. A method of testing patients is for them to walk up a flight of thirty steps ; indications to be looked for are an anxious expression, a respiratory rate of thirty-five or over, which persists while the patient lies and is interrogated from time to time, a pulse rate which fails to fall within five beats of the pre-exercise level on lying for two minutes.

All the men who are not excluded so far are treated with graduated exercises ; selected army exercises are used, with which the men are mostly familiar, and these are supplemented by route marches in light or full kit. The exercises are arranged in seven groups of increasing severity, and a patient moves to a higher grade every three or four days. The exercises last fifteen or thirty minutes daily. The men are classed for duty on the highest grade of exercise they are able to stand without distress. The average period required for classifying the men is a month and a half. Of 220 soldiers discharged from the hospital, 182 (83 per cent.) were still fit for duty in one capacity or other three months afterwards.

Prevention. A long and gradual training is advisable in recruits whose occupations have been sedentary, for these form a very high proportion of the patients, a longer convalescence from febrile affection or affections of the bowel, with a graduated system of retraining.

Treatment. This consists in clearing up local foci of infection (extraction of carious teeth, removal of tonsils, etc.). The removal of a latent dysentery

infection by emetine bismuth iodide has several times ameliorated the condition. If the symptoms are recent, a period of rest from drill and exercise is desirable, but rest in bed is harmful, and should always be avoided, except in severe præcordial pain, headache, or giddiness. Occupation is clearly called for, especially in the open air, such as gardening. They should be encouraged by the assurance that their malady is curable, and that improvement is visible. No particular attention should be paid to the heart. Tobacco increases the resting pulse rate and the symptoms after exercise. Bromides are valuable in the early stages. The most important treatment is by graduated exercises. Digitalis is valueless.

CONGENITAL MALFORMATIONS

Malformations of the heart arise from defects in its development, which is normally not complete until the closure of the ductus arteriosus and foramen ovale some days after birth. Arrest of this process in any stage will lead to a congenital malformation. It has occurred so early as to leave the heart with only two cavities—an auricle and a ventricle; or with three cavities—a ventricle and two auricles. But these are very rare cases, and the children mostly live but a short time after birth. One of the commonest lesions is a combination of pulmonary stenosis and deficiency of the interventricular septum. The stenosis is caused either by union of the pulmonary valves, or by a constriction of the ring just below them, or of the infundibulum itself, or by an imperfect septum dividing the infundibulum from the ventricle. Such conditions are regarded by Keith as invariably due to defects in development or to want of expansion of the bulbus cordis, and never to intra-uterine endocarditis. If the outlet of the right ventricle is thus obstructed in early foetal life, the pressure in that cavity is relieved by overflow into the left ventricle through the still unclosed septum; and this opening then becomes permanent. According to the stage of development at which the arrest has taken place, the deficiency may be a very large one or a mere perforation in the upper part; and in this latter case the aperture occupies the *pars membranacea*. When the deficiency is a large one, the aorta frequently arises from the right ventricle, or from both right and left ventricles, and the foramen ovale and ductus arteriosus may one or both be pervious. Both pulmonary stenosis and patent interventricular septum may occur independently of one another. In a few rare cases the communication between the two ventricles has been below the anterior aortic valve (over which arises the right coronary artery) instead of the right posterior valve; it is then in front of the *pars membranacea* and opens into the infundibulum of the right ventricle (27).

Constriction or obliteration of the aortic orifice or of one auriculo-ventricular orifice sometimes occurs, and similarly interferes with the course of the circulation and the normal development of the heart; and complete transposition of the aorta and pulmonary artery and other complicated transpositions of vessels have been found.

The ductus arteriosus and the foramen ovale may remain unclosed without any obvious reason—probably, however, from a temporary obstruction to the circulation at the time of birth; but more or less patency of the foramen ovale occurs in about 30 per cent. of healthy persons, a mere fissure or narrow valvular opening being insufficient of itself to allow of any free passage of the blood from one cavity to the other.

Instead of three sigmoid valves in the aorta or pulmonary artery there may be only two, or there may be four. This change may exist in association with other deformities, but if alone it is less likely to give rise to difficulties at birth than to lay the foundation of disease in later life.

Pathology. No more is really known of the cause of arrested or faulty development of the heart than of congenital malformations in other parts of the

body. One of the most characteristic symptoms of congenital heart disease is *cyanosis*, and the disease has been called the *morbus cæruleus*. Some recent observations have thrown light on the cause of cyanosis in general (14). (1) It is due to slow circulation of blood in the peripheral capillaries, so that the returning venous blood contains less oxygen than usual; (2) it is due to the arterial blood not being fully saturated with oxygen. Of course both these factors may be combined, and the cyanosis is intensified if the red cells of the blood are increased. There seems little doubt from determinations of the oxygen content of blood taken direct from the radial or brachial artery through a fine needle that, although in marked cases there may be some arterial unsaturation, it is the peripheral stasis factor that is chiefly responsible for the cyanosis of acquired heart disease. The arterial blood may contain less than the normal quantity of oxygen (a) if there is a hindrance in the lungs to the exchange of gases, such as may occur in œdema, pneumonia, bronchial spasm, or chronic pulmonary disease; (b) if the polycythæmia is extreme, because the blood may not remain long enough in the pulmonary capillaries for all the corpuscles to become normally saturated; (c) if the arterial blood is a mixture of blood from the lungs and from the systemic veins, as may occur with a deficient septum ventriculorum or patent foramen ovale, associated with congenital pulmonary stenosis. Slowness of the blood through the lungs, such as occurs in acquired heart disease, will by itself tend to complete saturation of the arterial blood, because there is plenty of time for oxygen to be taken up. It was found in certain cases of congenital heart disease with marked cyanosis that the arterial blood was only 70 to 80 per cent. saturated with oxygen. When the patient breathed pure oxygen for half an hour through a mask and valves, the saturation was raised to just over 90 per cent. This is compatible with the arterial blood being composed of a mixture of pulmonary and venous blood, because it was impossible to saturate it completely by giving oxygen. At the same time the peripheral stasis factor is also present in congenital heart disease and increases the cyanosis.

The common lesion is the association of pulmonary stenosis and deficient septum. The stenosis may be so extreme that very little of the blood can reach the lungs by this route. Nearly all of it passes into the aorta and mixes with blood from the left ventricle. In these extreme cases the bronchial arteries are dilated and a fair supply of blood reaches the lungs by means of the anastomoses of these arteries with the small branches of the pulmonary artery. In one case the pulmonary valve was found to be entirely closed and no systolic murmur was heard over the pulmonary area; the patient was extremely blue. The heart was only slightly larger than usual, since all the blood travelled into the aorta, and there was no extra resistance (14, Case 15). Where the pulmonary valve is patent, though stenosed, less blood will pass into the aorta; the right ventricle may be hypertrophied and dilated, and there will be a systolic murmur and perhaps a thrill in the pulmonary area. In certain cases a patent foramen ovale may act instead of a deficient septum in short-circuiting the blood. A patent foramen ovale or a patency of the septum will be of no functional significance if the pulmonary valve is normal, because there will be nothing to prevent the blood going through the lungs in the ordinary way. At most a little blood may pass through from the left to the right ventricle, and so travel through the lungs a second time. A patent ductus arteriosus associated with a pulmonary stenosis and deficient septum will provide an extra path for the mixed arterial blood to pass through the lungs; if present by itself it will be of little functional significance.

Symptoms. Cyanosis when present is most marked in the prominent parts of the face—the cheeks, lips, nose, and ears—and in the fingers and toes. In slighter cases it is only richer red than natural; in the severest cases it is purple almost to blackness, and any exertion at once increases the distension of the vessels and deepens the colour. It is a remarkable fact about this disease that,

though the cyanosis may be extreme, there is no shortness of breath while the patient is at rest. The chronic stagnation will cause thickening of the parts affected, and the nose and lips are coarse, while the ungual phalanges of the fingers or toes are thickened much beyond the rest of the fingers, or "clubbed" (see later). The blood shows in a remarkable degree the great excess of red corpuscles (*polycythæmia*) which is met with in many forms of cyanosis; thus the corpuscles have been found to number from 8,000,000 to 9,000,000 per cubic millimetre, and the hæmoglobin may reach 110 to 160 per cent. of the normal. The patient sometimes suffers from attacks of giddiness, faintness, convulsions, and loss of consciousness. He is incapable of much exertion, from the readiness with which dyspnœa supervenes; and he is also peculiarly susceptible to cold or exposure, and easily suffers from attacks of catarrhal bronchitis. In later stages œdema of the legs, ascites, enlarged liver, and albuminuria are found; or the patient succumbs to bronchitis; or tuberculous disease of the lung is the cause of death.

Physical Signs. Most commonly a systolic murmur is heard, loudest over the pulmonary area in congenital pulmonary stenosis, but it may also be heard over adjacent spaces. It may be accompanied by a thrill. Dulness may extend to the right of the sternum in consequence of the dilatation and hypertrophy of the right side of the heart. In pure pulmonary stenosis this is very marked. If deficiency of the septum is the only lesion, there is a systolic murmur of maximum intensity in the third left space near the sternum, conducted outwards, and often a thrill; but no cyanosis. A patent ductus arteriosus often causes a prolonged murmur running through systole into diastole, and waxing and waning in loudness. (See Plate 10, E, p. 220.)

The various types of congenital heart disease may give characteristic appearances when examined by X-rays. Thus in the rare pure pulmonary stenosis the shape of the heart is characteristic (see Plate 12, B), owing to hypertrophy of the right ventricle, and dilatation of the right auricle. There may be dilatation of the pulmonary artery beyond the obstruction; the reason for this is quite obscure, but it has been several times observed at post-mortems. In the usual combination of septal defect with pulmonary stenosis both left and right sides of the heart may be enlarged; but, on the other hand, there may be no recognisable change in the shape of the heart.

Prognosis. Congenital malformations are always unfavourable. Cases of severe defect live but a few hours or days; others of slighter degree survive five, ten, or twenty years; and even persons with very ill-developed organs have occasionally reached middle age. In any given case the prognosis must depend upon the evidences of cardiac efficiency rather than the nature of the malformation.

Treatment. This is the same as for chronic cardiac disease.

DISEASES OF THE PERICARDIUM

PERICARDITIS

Ætiology. Inflammation of the pericardium may result from a general blood infection, or it may occur from local irritation or from infection directly spreading from the neighbourhood.

Among the first class of cases, acute rheumatism is its most frequent cause; but it also occurs in Bright's disease, in pyæmia, in leukæmia, in tuberculosis, in influenza, in general pneumococcal infection, and in other conditions of septicæmia and toxæmia. Its local causes are the growth of cancer nodules into its cavity, the rupture into it of abscesses and hydatid cysts, and the contiguity of a source of infection, such as empyema or pneumonia.

Morbid Anatomy. If we take as the type the pericarditis which

occurs in the course of acute rheumatism, we find the following changes : In early stages the membrane loses its smooth, glossy surface, and becomes more vascular, so that it is injected with a fine network of vessels. Some shreds of lymph from the exudation of corpuscular elements and fibrin from the blood vessels are next seen, and a complete layer forms upon the pericardium. Ultimately the two opposed surfaces of the sac may be separated by a layer of lymph $\frac{1}{8}$ or $\frac{1}{4}$ inch in thickness, which is sufficiently soft to allow the parietal and visceral membranes to be peeled from one another, and the lymph is often of such a consistence that the separation of the surfaces leaves a curiously honeycombed or reticulate appearance. Generally, at the same time, some serum is formed, of yellow colour, and turbid from corpuscular elements. This may accumulate to a considerable amount and further separate the two layers of the pericardium, while it allows the formation of long, shaggy processes of lymph, stretching from surface to surface. After a time the fluid generally disappears, and the lymph is either itself absorbed, or it becomes organised, and unites the parietal and visceral layers of the sac more or less completely together, causing adherent pericardium.

In other infections, and especially in pyæmia or septicæmia, the fluid contents of the pericardium are pus, instead of serum, constituting *purulent* or *suppurative pericarditis*. This is often secondary to abscess of the cardiac muscle, which is known frequently to result from acute necrosis of the long bones. Sometimes the new-formed vessels in the inflammatory formation rupture, and small petechiæ or larger patches of hæmorrhage cover the surface of the membrane, forming *hæmorrhagic pericarditis*. And, occasionally, tubercles are formed both in the new tissue and in the original membrane covering the heart's surface ; this is known as *tuberculous pericarditis*, and forms part of a general tuberculosis.

The micro-organisms of pericarditis vary with its origin. Streptococci, staphylococci, pneumococci, and tubercle bacilli have been most often found. Poynton and Paine found their rheumatic diplococci in the pericarditis of rheumatism.

Effect on Circulation. Cohnheim's animal experiments show that the effect on the circulation depends on the tension in the pericardial sac. If fluid is injected slowly when the pressure reaches a definite point the arterial pressure falls, and the venous pressure rises. This is an expression of a diminished efficiency on the part of the heart as a pump, the output of blood at each beat being diminished. The higher the tension in the pericardium, the smaller the output.

Physical Signs. Since pericarditis so frequently arises in the course of some infectious disease, like rheumatism, its symptoms may be entirely masked by those of the disease which it accompanies, and its presence may be only revealed by the alteration in the heart sounds, and other physical signs which it produces. These, however, are generally characteristic. Firstly, there is the *pericardial rub*, which has been described under the examination of the heart. It may be soft to begin with, but after a few hours the sound becomes louder and harsher and rougher, and then the friction can often be felt by the hand placed over the præcordial region.

If liquid is effused into the pericardium, as is frequently the case, the præcordial dulness is increased. It extends upwards to the upper border of the third rib, the upper border of the second rib, or even to the clavicle ; towards the right for 1 inch or more beyond the sternum ; and towards the left it may reach right into the axilla. The præcordial dulness has a more or less triangular shape, with its broad base upon the diaphragm, and a rounded apex at the upper part of the sternum and the left upper intercostal spaces.

As the liquid increases, the impulse of the heart becomes diffuse. An important distinction must here be mentioned between pericarditis and pleurisy in the effect of effusion of liquid on the occurrence of a friction sound. In pleurisy the effusion of liquid results in the disappearance of the pleuritic friction sound. In pericarditis the friction sound persists commonly throughout the illness, even to the

period of greatest distension of the sac, and during the subsequent absorption of the liquid. This is probably because the fluid collects chiefly behind the heart, as the patient lies on his back, leaving the two inflamed layers of pericardium rubbing against one another in front.

A pericardial effusion often compresses the base of the left lung, causing a dull note on percussion and bronchial breathing on auscultation.

Another result of pericarditis in some cases is inhibition of the action of the diaphragm. Either abdominal respiratory movements cease, or there is a little recession during inspiration, with upward movement of the higher abdominal viscera and of the heart, collapse of the bases of the lungs, and it may be distension of the stomach and colon.

Symptoms. The local symptoms which may accompany pericarditis and pericardial effusion are pain, anxiety or distress at the præcordia, tenderness on pressure over that region, shortness of breath, with shallow respirations and short hacking cough. The pulse may not at first be much affected, but it tends soon to be quick. Occurring in the course of a febrile disease like rheumatism, pericarditis may not notably add to the existing pyrexia, but with its rapid onset occasionally there is considerable elevation of temperature—for instance, to 105° or 106°; and in other cases it may be accompanied by the usual conditions of pyrexia, loss of appetite, dry tongue, thirst, and scanty urine.

In the worst cases the cardiac feebleness increases, the pulse becomes irregular and fluttering, or may take the form of the *pulsus paradoxus* (see p. 226), præcordial pain is severe, and the face becomes drawn and pinched and the patient dies primarily of cardiac failure, sometimes with convulsions and coma. But in the majority of instances the symptoms gradually subside; the dulness diminishes while the rub often remains till a late stage. The changes of pericarditis occur rapidly, effusion may reach its height in two or three days, and subsidence may be well established in three or four more.

Suppurative, tuberculous, and hæmorrhagic pericarditis are not essentially different in their symptoms and physical signs.

Diagnosis. Under ordinary circumstances this presents no difficulties, the double or triple friction sound being very distinctive. The diagnosis of pericardial effusion is not always easy, because it may be simulated by a *dilated heart*, caused by the same rheumatic poison as has led to the pericarditis. The signs which support the diagnosis of effusion are extension of dulness to the left beyond the heart's impulse and upwards to the second rib or higher, and signs of compression at the left base. The Röntgen rays may show the shadow of the heart and pericardium extending right out to the left costal wall, and up into the first space, and to the right as far as the nipple, with little or no pulsation, and with a large effusion the heart's shadow is sometimes seen within a ring of lighter shadow due to the distended pericardium alone.

Prognosis. Pericarditis is not, on the whole, an immediately fatal disease. It may be so mild that it is only detected by the stethoscope in the course of a routine examination, and in a large proportion of the cases occurring in rheumatic fever the inflammation subsides. The adhesion of the layers, which so often results, may become a danger in itself. On the other hand, the commonness of "milk spots" found on the surface of the heart at post-mortems suggests the possibility that slight attacks of pericarditis frequently occur, and subside completely. Milk-spots are often regarded as merely due to friction; but it is difficult to see how the latter can occur without some degree of inflammation. Possibly some are the result of bruising from trauma. In Bright's disease, and in association with other chronic cachexial conditions, pericarditis often occurs towards the end of the illness, and then may appear to be the lesion determining death; but even in such circumstances the physical signs may completely disappear before death, or, if they persist, the fatal result may not seem to be hastened thereby. A grave prognosis must be given in suppurative pericarditis,

and the occurrence of a pneumococcal pericarditis in the course of pneumonia or empyema is generally fatal ; but Sir F. Taylor knew a case of double empyema with pericarditis recover. Pericarditis in acute rheumatism is often accompanied by, and masks, some inflammation both of the endocardium and of the myocardium, the ill effects of which become developed afterwards.

Treatment. The treatment of pericarditis is mainly palliative. Like other acute inflammations, it must be met by complete rest in the recumbent or semi-recumbent posture, by nutritious easily digestible diet, and by abstinence from excitement. In the case of rheumatic fever, these conditions are probably already provided in the treatment of the initial disease. For very severe pain six or eight leeches may be applied to the præcordia. The præcordia may be covered by a layer of cotton wool, or a warm linseed-meal poultice, or anti-phlogistine or thermogen wool may be applied. Morphia may be given if necessary. If the circulation is failing, or the heart becomes irregular, small doses of tincture of digitalis should be given frequently, with brandy or ammonia. A rheumatic effusion rarely if ever requires aspiration ; but this must be considered if there is a possibility that pus is present. D. C. Taylor, from experience at Lewisham Hospital, after anæsthetising the skin and subjacent tissues with 2 per cent. novocaine, recommends inserting a fine needle backwards and a little downwards in the 6th intercostal space at the left side of the sternum, in order to avoid wounding the internal mammary vessels, until the diaphragm is felt—to be sure of this the patient is told to take a deep breath ; it is withdrawn a little and then pushed straight back for about an inch from the surface. He then washes out the cavity several times with 20 c.c. of 1 in 2,000 flavine, and the aspiration is repeated every other day or a rib may be resected.

ADHERENT PERICARDIUM OF RHEUMATIC ORIGIN

Morbid Anatomy. Reference has been already made to this condition as arising from rheumatic pericarditis. The degree to which the two surfaces may adhere varies much in different cases ; there may be merely a few filaments running from the surface of the heart to the parietal pericardium, or there may be complete union of the pericardial sac to the surface of the organ, and every intermediate condition occurs. When the union is complete, the tissue uniting the two surfaces may form only a thin layer ; or it is a dense, firm, fibrous, more or less vascular coat, $\frac{1}{4}$ inch or even $\frac{1}{2}$ inch in thickness. Hypertrophy and dilatation are usually present, because the muscular substance of the ventricle has been injured by the occurrence of myocarditis at the same time as the pericarditis ; there is usually mitral stenosis. In many cases there is not only obliteration of the pericardial sac, but the external surface is firmly fixed to the surrounding pleura and to the sternum. In fact, the mediastinal tissues are matted together to form dense fibrous tissue (*mediastinitis fibrosa*).

Symptoms and Physical Signs. Cardiac pain, palpitation, and dyspnœa are prominent. Physical signs cannot be relied upon to reveal the presence of the adhesion itself ; but when the more extensive external adhesions are also present, one or more of the following physical signs may be recognised : (1) systolic retraction at the point corresponding to the apex of the heart ; (2) systolic retraction of the lower end of the sternum ; (3) systolic retraction of the third, fourth, and fifth intercostal spaces to the left of the sternum ; (4) systolic retraction of the lower ribs at the side or back of the left chest (Broadbent's sign). These are not very reliable ; certainly systolic retraction of intercostal spaces is not peculiar to adherent pericardium. The commonly associated mitral stenosis must be carefully looked for. Death is caused by heart failure with extensive œdema.

X-rays may give valuable indications of adherent pericardium. They consist in alterations of the normal movement and shape of the heart on breathing deeply

or leaning to one side, and alterations in the movement of the central part of the diaphragm on breathing, due to adhesions with the pericardium and mediastinum.

The **Prognosis** and **Treatment** of pericardial adhesions must be considered chiefly in reference to the changes in functions of the heart which result from them (*see pp. 275, 276*). The treatment is that of heart disease in general.

CHRONIC CONSTRICTIVE PERICARDITIS

Pick's Disease

This disease, first noted by Lower (1669), Chevers (1842), Wilks (1870) and Pick (1896), has just recently been again brought to light (73).

Ætiology. Tuberculosis, pneumonia with pleurisy and pericarditis or sepsis may be responsible; but the cause is often unknown, since the onset is insidious; there may be a history of pericarditis, but not of acute rheumatism.

Morbid Anatomy. There is chronic fibrous thickening of the parietal pericardium, often with calcification, pockets of fluid, obliteration of the sac and/or external pericardial adhesions. Since, owing to the constriction, the heart cannot fill in diastole, "inflow stasis" results, and there is ascites, often with a frosted "sugar loaf" liver or spleen, and pleural effusion. The heart itself is healthy.

Symptoms. The onset is insidious; there are dyspnoea, ascites, an enlarged, but not a tender or pulsating, liver, engorgement of the jugular veins, pulsus paradoxus, low blood pressure, and sometimes oedema of the legs and pleural effusion. The size of the heart is normal or a little increased. Broadbent's sign is not present. The electrocardiogram is of low voltage with flattening or inversion of the T-waves in leads I. and II., and occasionally auricular fibrillation. The serum proteins may be low.

Diagnosis. Mitral stenosis with or without adherent pericardium is differentiated by careful examination for the murmurs. Polyserositis is a different disease. Portal cirrhosis and nutritional oedema must be differentiated.

Prognosis. The disease is chronic, sometimes with remissions; it may run a rapid course or last for many years. Six out of 10 cases have been cured after operation, and one other relieved.

Treatment. Delorme's operation of pericardial resection is the only cure.

HYDROPERICARDIUM

This term denotes the presence of an excess of serum in the pericardial sac, and is generally used to distinguish the passive secretion of dropsy from that of inflammatory effusions already described under Pericarditis. The pericardium naturally contains a very small quantity of serum, and after death from any cause it is common to find a few drachms of pale yellow fluid in it. The causes of serous effusion, apart from inflammation, are those of general dropsy, such as Bright's disease, and such local interference with the venous circulation of the pericardium as valvular disease of the heart itself, chronic lung disease, and pressure of growths upon the veins which return blood from the pericardial surfaces. The liquid contained in the sac resembles that of dropsical effusion into the other serous cavities, being pale yellow, or more or less pink from exudation of blood-colouring matter, with a small quantity of fibrinogen and from 1 to 3 per cent. of albumin.

The **Physical Signs** of hydropericardium are the same as those of effusion in pericarditis. As a rule, no special **Treatment** directed to the pericardium is required where the condition forms part of a general dropsy, or where it results from local interference with the circulation; the general dropsy or the valvular

disease must be dealt with. In rare cases the effusion may be so rapid or abundant as to require paracentesis of the pericardium.

PNEUMO-HYDROPERICARDIUM

This signifies the presence of gas and liquid together in the pericardium. Gas in conjunction with liquid has been observed as a result (1) of gas gangrene, and (2) of the communication of the pericardial sac with air-containing cavities. This communication may be traumatic, as in the case of a juggler who, in attempting to swallow a blunt sword, perforated the pericardium from the œsophagus; as in the case recorded by Flint, where the pericardium was punctured by a stab through the pleura; and after the operation of paracentesis pericardii. Or the communication may be effected by disease; and cases are on record of cancer of the œsophagus ulcerating into the pericardium, of a phthisical cavity opening into it, and of a hepatic abscess communicating at the same time with the pericardium and with the stomach. Gas can never be observed alone in the pericardium, as its entrance from without is almost immediately followed by pericarditis with liquid effusion.

The **Physical Signs** of pneumo-hydropericardium are resonance on percussion over the præcordial area and splashing, churning, or gurgling sounds, synchronous with the movements of the heart.

HÆMOPERICARDIUM

In slighter degrees, the effusion of blood into the pericardium occurs in so-called hæmorrhagic pericarditis, from the rupture of the new-formed vessels; but larger quantities, when not directly traumatic, result from rupture of the myocardium, of an aneurysmal sac, or of vessels in a cancerous growth. Scurvy and allied conditions may also give rise to pericardial hæmorrhage.

Symptoms. When sudden effusion of blood into the pericardium takes place, the patient is seized with more or less oppression of the chest, pallor, syncope, unconsciousness and death in quick succession; or with pallor, feeble pulse, and orthopnœa he may remain for twenty-four or thirty-six hours before the fatal termination; or presumably, with a less degree of hæmorrhage, death may be still further delayed, and a pericarditis may develop which contributes to the final result. Walshe refers to cases, probably of a scorbutic nature, or at any rate not dependent on rupture of aneurysms, or of the heart itself, in which recovery has taken place.

The **Physical Signs** are those of a large pericardial effusion, extensive præcordial dulness, and enfeeblement or absence of the heart sounds. The **Diagnosis** would be assisted by a knowledge of the previous existence of aneurysm, or attacks of angina pectoris.

Treatment. Absolute rest and judicious use of stimulants would give the only chance.

ANGINA PECTORIS

This name is commonly given to an intense pain beneath the sternum produced in the heart or aorta, which comes on with great suddenness, and occasionally proves fatal. There is probably no fundamental distinction between this severe pain and other milder pains produced in the heart, which are sometimes designated "angina minor," or better—simply "cardiac pain."

Ætiology. It may occur in boyhood, but it is uncommon before the age of thirty, increases in frequency with every year, and is most common between the ages of fifty and seventy-five. It is more frequent in men than in women, in the proportion of about four to one. Heredity also has an influence. It is common in aortic disease, rare in mitral stenosis. Tobacco is not uncommonly respon-

sible. Focal sepsis, especially in the gall bladder or at the apices of the teeth, is another factor. The immediately exciting causes are: (1) Physical exercise, especially going uphill or against the wind, and, later on, even the mildest forms of exertion; (2) a large meal; very often these two factors are combined; (3) emotional excitement, whether depressing or exhilarating, and mental strain; and (4) exposure to cold. The last is important, since undressing at night in a cold room may bring on an attack in bed. Occasionally the attack begins during sleep.

Pathology. When death has taken place in an attack, the heart has generally been found relaxed, with its cavities full of blood. In the majority of cases, some disease of the heart or aorta has been found, and mostly of the following kinds: myocarditis, pigmentary, fatty or fibroid degeneration of the myocardium; syphilitic aortitis, atheroma, or dilatation of the aorta; atheroma or calcification or shrinkage of the aortic valves; and arterio-sclerosis or calcareous deposit in the coronary arteries, or their obliteration from endarteritis or thrombosis. Coronary embolism may cause death rapidly, with the most severe anginal symptoms. In some cases of death from angina the heart muscle and coronary arteries have been found to be perfectly healthy.

Mackenzie's view is that angina depends on the cardiac muscle (29). In this connection it may be noted that the usual pain in mitral stenosis, which arises in the left auricle, occupies a band on the left side of the chest, extending from the nipple to below the ensiform cartilage; the sensory nerves from the skin of this area pass to the sixth and seventh dorsal segments of the spinal cord. Pain arising in the ventricle and aorta, on the other hand, is felt higher up in the chest, over an area corresponding to the higher dorsal segments, because, in the embryonic cardiac tube, the ventricular part lies anterior to the auricular part, and becomes bent over and downwards later on (30). The theory that anginal pain comes from the ventricle is now generally accepted. The fact that pain is sometimes caused by a healthy cardiac muscle need cause no more difficulty than the pain which is often produced by healthy gastric muscle when there is pyloric stenosis. Cardiac pain is due to hard work of the cardiac muscle with an insufficient supply of oxygen, and it seems reasonable to suppose that the muscular fibres must be sufficiently healthy to be able to produce it; they must be capable of hard work. The substernal pain felt by healthy but untrained persons during a hard game of football may be of similar origin. Angina may occur with fibroid heart because, though healthy, the muscle fibres are greatly reduced in number by replacement with fibrous tissue. Angina may occur, while there is no breathlessness on exertion, because the muscle, though overworked, still keeps up the circulation. When the circulation fails angina may disappear, to reappear when the circulation is restored by treatment. However, the commonest condition is, undoubtedly, the simultaneous occurrence of both pain and breathlessness after exertion. On the analogy of experimental pain produced in a limb by muscular work when the circulation is arrested (see intermittent claudication), it has been suggested that arterial spasm is the origin of angina and this liberates a P-substance in the tissue which causes a steady pain not varying in intensity with the heart-beats. The P-substance may be incompletely oxidised metabolites of low molecular weight, which act by the osmotic pressure they produce and disappear fully oxidised, when the oxygen supply returns. Amyl nitrite, which relieves all but the severest type of pain (*i.e.* that due to infarction) in a few seconds, acts by dilating the coronary arteries and in some patients alters the electro-cardiogram, making the T-wave upright (28). It also increases the pulse rate, but though it causes a peripheral vaso-dilatation, with marked flushing of the face, this cannot be the cause of the relief, because it often happens that the relief occurs before the blood pressure falls. In a case of mitral stenosis and regurgitation, with pain beneath the nipple, amyl nitrite also caused relief.

Symptoms. The patient is seized quite suddenly with acute pain in the front of the chest, situated beneath the upper or lower part of the sternum, or rather to the left-hand side of it, but not over the heart itself. The pain radiates thence to the left side and back, or through to the scapula; up to the left shoulder, and down the left arm to the hand; or less frequently the pain is on the right of the sternum and radiates to the right shoulder, arm, and hand. The pain may occur simultaneously on the right and left side. It may ascend on either side of the neck as high as the scalp, and this is explained by the fact that the trigeminal nerve is the sensory counterpart of the afferent vago-glosso-pharyngeal nerve from the heart and so becomes the seat of "referred pain" (30). The pain may be felt in the throat. The pain in the chest is described as "tearing" or "piercing," or "burning as hot as fire," or "constricting." Tingling or numbness may accompany the pain in the arms or fingers. There is considerable variety in the onset of the pain in different cases: thus it may begin in the arm or arms and spread up to the chest; or it may begin in the upper abdomen (epigastric angina) or lower down in the abdomen (angina abdominis). In one such case the pain was brought on by exertion, was most severe in the umbilical region to which it was at first confined; but it gradually increased in severity, and spread all over the front and back of the chest. During the attack the patient's expression is anxious or solemn; he is obliged to stop if he is walking, and he remains quiet; he becomes covered with clammy perspiration; the saliva may be increased; there may be a sense of impending death. The pulse is usually unaltered, but it may be slowed, or irregularities such as extra systoles may be noticed; it becomes quick towards the end of a fatal attack. There is no characteristic alteration in the blood pressure; in some cases it is raised by 20 mm. or so. After lasting a few seconds or minutes, the pain quickly passes off, but it may occur again frequently in the course of a few hours, or it may not be experienced again for several months or years. Angina may be fatal in the first and only attack. Between the attacks, and lasting for weeks after the severe attacks have finally ceased, tenderness may be experienced on pressing various spots on the chest wall and arms. These spots vary from day to day. At the same time the patient's attention may be drawn to sensations of fulness or compression inside the chest, which should be regarded as warning signs that the severe pains may come on unless care is taken.

The attack is often accompanied by a feeling of fulness in the stomach, particularly if it is brought on by exercise after a meal, and it may be relieved if wind is successfully eructated. The frequency of this symptom has led to the view (31), which, however, few people accept, that the primary cause of the trouble is distension of the stomach or œsophagus with wind. In one observed case (32) attempts at eructation regularly relieved the pain, but it was found by X-rays that air had entered the stomach. There is, however, a very close reflex connection between the seat of angina and the upper alimentary tract, since a full meal will precipitate an attack, and some of the pains felt during anginal attacks are produced in the œsophagus, and may be momentarily accentuated or relieved by swallowing. This is to be explained by the peristaltic wave which passes down the œsophagus after swallowing (32). John Hunter made a clinical observation on this subject in his own case. The term "pseudo-angina" may perhaps be used for such pains. Angina is sometimes associated with Raynaud's disease.

In angina minor, the patient, as the result of exercise or of exposure to cold, may feel some substernal pain for a few seconds, and be obliged to remain still. These attacks have sometimes incorrectly been called "pseudo-angina"; but this term should not be used in this connection, as it tends to mask the gravity of the condition.

Diagnosis. The character of the pain, its occurrence as the result of exertion, its relief by amyl nitrite, and the evidence of a cardiac or arterial lesion (valvular disease or arteriosclerosis), are generally conclusive. It must be distinguished from cardiac pain felt over the præcordia, which is so common an

accompaniment of a heart failing from valvular disease or myocardial degeneration. It must be distinguished from neuralgic pains, especially in neurotic women. In this case the pain often occurs during rest, lasts much longer than angina, and may be accompanied by tumultuous action of the heart and palpitation. The milder forms of angina are frequently mistaken for indigestion, or gastritis; and this is partly accounted for by the fact that an attack often occurs when the patient gets about after a meal. Tobacco angina presents rather similar features to angina pectoris. Very severe pain may be caused by thrombosis of a coronary artery as described later. The pain, however, is continuous; the patient is dyspnoëic and often restless. The pulse becomes feeble; there is pyrexia and a leucocytosis and sometimes pericardial friction which settles the diagnosis. Finally, acute distension of the stomach has caused similar symptoms, and this has been relieved by passing a tube into the stomach.

Prognosis. Death may occur during, or shortly after, an anginal attack, or during sleep, or suddenly. It may occur from heart failure or independent causes. The outlook depends on how well the case responds to treatment. A patient may have an attack and yet with proper care live for years afterwards. Unfavourable signs are a poor response to exercise, pulsus alternans, and certain alterations in the electro-cardiograms (*see* p. 231), which all help to indicate that the functional power of the heart is below par.

Treatment. The patient must remain quite still during an attack. The most efficacious drug for an attack of angina is nitrite of amyl. From 3 to 5 minims are contained within a small glass capsule, covered with linen: the capsule is crushed between the finger and thumb or forceps, and the vapour is inhaled freely. The face flushes, the cranial vessels throb, and the pain is often relieved at once. The dose may have to be repeated. A good effect is also obtained by placing a tablet of nitro-glycerine gr. $\frac{1}{100}$ to $\frac{1}{12}$ in the mouth and chewing it, when absorption takes place. The first administration of even small doses of nitro-glycerine is often followed by a throbbing headache, but after a time tolerance is established, and the larger doses can be borne. Sodium nitrite ($2\frac{1}{2}$ grains in tabella) and erythrol tetra-nitrate (1 grain in 1 drachm absolute alcohol suitably diluted) are also good vaso-dilators. If these measures fail, the hypodermic injection of morphia may be used; and much collapse will require brandy or ether. Morphia is specially useful when the attacks are precipitated by excitement or mental anxiety. Sal volatile diluted with an equal volume of water may be useful when the attacks are precipitated by a full stomach or are accompanied by flatulence. Repeated attacks have been stopped by the oxygen tent.

When angina has once declared itself in a patient, absolute rest in bed for some weeks and freedom from anxiety and excitement will be required. Food should be given in small amounts at a time. On getting about again the patient's life must be altered so as to avoid those factors—excessive muscular exertion, etc.—that have caused the attack. In regulating his life he will be helped by the premonitory sensations of fulness and compression in the chest which will appear if he is again beginning to do too much. The attacks should be arrested in the first place by drugs; but later on it is probably best not to use nitrites prophylactically, as they may remove the patient's warning signs, so that he may be led to overwork his heart again, and this may lead to circulatory failure. Amyl nitrite or tablets of nitro-glycerine should be carried for an emergency. Smoking in excess must be stopped; some patients are so sensitive to tobacco that one or two cigarettes a day may keep up attacks. In severe cases, where the reserve of the heart is low, such treatment may fail to ward off attacks, and these will still come on whenever the patient gets about at all. In such a case nitro-glycerine will be valuable; the dose may be $\frac{1}{100}$ minim three or four times daily, gradually increased to $\frac{1}{20}$ or $\frac{1}{10}$. Iodide of potassium (5 to 30 grains) is also beneficial in some cases. Syphilis must be treated as already described. In

diabetes mellitus a high carbohydrate diet and insulin should be given. The exposure of the body surface to light from the electric arc has sometimes warded off attacks. Ammonium bromide in doses of 10 to 20 grains is useful as a mental sedative. Surgical treatment, *i.e.* division of the depressor nerve, etc., is not to be recommended in the present state of our knowledge.

The association which has been found between angina and acute engorgement of the heart and lungs from left-sided failure suggests that forcible expiration against a closed glottis may stop an attack by emptying the heart and lungs into the systemic circulation. Personal observation of the writer proves that this is the case, at any rate, for mild left-sided pains. Slow deep respirations are also useful. The reversed process of forcible inspiration *may* have an application for certain right-sided pains. The patient should be taught to carry out these manœuvres; they can certainly do no harm.

INFECTIVE ARTERITIS

Acute Arteritis. Acute infection may approach the artery from without (*initial peri-arteritis*) or from within (*initial endarteritis*). The former is caused by the direct spread of the infecting agent from some neighbouring suppurative focus or wound. Initial acute endarteritis of the larger arteries may be due to invasion of the wall by organisms carried in a septic embolus which has become impacted in the lumen or to spread of infection from adjacent septic vegetations as in malignant endocarditis affecting the aortic or pulmonary cusps. By whatever route the infecting agent reaches the vessel wall, the whole thickness of the latter may speedily become involved. Histologically, the appearance will be that of acute inflammation, and, depending on the degree of damage, the softened wall may bulge (*mycotic aneurysm*) or may perforate allowing blood to escape.

Polyarteritis Acuta Nodosa. Having used the term acute peri-arteritis, mention may fittingly be made here of a very rare condition (also called peri-arteritis acuta nodosa), the more so as it is also probably due to an acute infection, although the nature of the latter has not been determined. Many of the small arteries in the body may be affected, especially those of the heart and kidneys. The affected vessels are the seat of small nodular swellings, which are really small aneurysms with or without an accompanying thrombosis. The initial lesion appears to be a focal necrosis of the media with a surrounding acute inflammatory reaction which involves all three coats. Thrombosis may occur or the softened wall yields, bulges outwards (aneurysm) and frequently ruptures, allowing blood to escape.

Tuberculous Arteritis. The two commonest causes of chronic infective arteritis are the tubercle bacillus and the *Treponema pallidum*. In the vicinity of a *tuberculous* focus the wall of an artery may become involved as a result of the direct extension of the caseo-granulation process. The affected wall shows the usual features of a tuberculous lesion, and the lumen may become obliterated by proliferation of intimal or endothelial cells with or without a concomitant thrombus.

Syphilitic Arteritis. In the case of *syphilitic* arteritis two forms are distinguished, one as found in the aorta and the other as it occurs in the small arteries, but the underlying reaction is the same in both. In the former the inflammatory process instigated by the treponema starts in the adventitious coat in relation to the vasa vasorum whose lumen becomes narrowed or obliterated by a proliferation of its lining endothelial cells. The perivascular round-celled infiltration follows the course of the vasa vasorum and so spreads into the middle coat of the aorta. Small areas of muscle cells and elastic tissue undergo necrosis, and with the foci of lymphoid and plasma cells constitute microscopic gummas. The intima in relation to such an area becomes thickened by proliferation of the intimal cells and vascularised by the budding of young capillaries, which grow into the thickened area. Later, as the result partly of absorption of the necrotic

débris and partly because of contraction of the young fibrous tissue which replaces the vanished musculo-elastic tissue, scarring is seen on the inner surface of the aorta. In this way inelastic fibrous tissue replaces the musculo-elastic tissue of the media on which the efficiency of the arterial wall depends, and the latter, where fibrosed, gradually becomes stretched. This is the genesis of an aneurysm. Owing to the fact that the gravity of the lesion depends on the amount of damage to the middle coat, syphilitic disease of the aorta is frequently spoken of as a *mesaortitis* although it is primarily a lesion of the *vasa vasorum*.

The affected aorta will show patches of thickening as well as very definite scarring, and it is this latter that serves to differentiate macroscopically a syphilitic lesion from the lesions due to atheroma which, of course, may also happen to be present.

In the case of the small arteries the adventitious coat also shows a small round-celled infiltration. The media is little affected, but the intima shows very definite changes. It becomes greatly thickened as a result of proliferation of the connective tissue cells of the intima. Fibrous laminae and new elastic tissue are laid down and the lumen becomes greatly narrowed and even obliterated. This process of obliteration may be hastened by thrombus formation. A favourite site for this form of syphilitic disease is the brain-vessels, especially the cortical branches. Syphilitic endarteritis plays an important part in relation to the necrosis which occurs in gummas, and, on the other hand, a gummatous process may, by direct extension, come to involve a small artery in the vicinity hitherto unaffected.

Thus tuberculous and syphilitic endarteritis both tend to bring about obliteration of the lumen and hence they are examples of what is called *endarteritis obliterans* or *proliferans*—a process which may be brought about in other ways than those just mentioned. For example, the term may be applied to the physiological closure of arteries that are no longer necessary. This happens in the case of the umbilical arteries, the ductus arteriosus, many of the uterine vessels after parturition, the ovarian vessels at the menopause, etc. In these cases there is a gradual thickening of the intima, the lumen becomes obliterated and the muscle cells undergo atrophy.

Thrombo-angiitis Obliterans. Another type of endarteritis goes by the name of thrombo-angiitis obliterans. This particular type of arterial disease occurs chiefly among adult Jews of young or early middle age, especially those from Eastern Europe. It is not due to syphilis, but excessive cigarette-smoking may be partly responsible. The blood pressure is not raised. The exact pathogenesis is not clear. There is, however, considerable proliferation of the cells of the intima, which accordingly becomes progressively thicker. Along with this or antecedent to it thrombosis occurs, and later the thrombosis becomes organised. There are no inflammatory changes in the outer coat, and only occasionally does the middle coat show degenerative changes. The nutrition of the part supplied by the diseased artery, though defective, is still possible. Intermittent claudication and erythromelalgia are characteristic symptoms.

Periarteritis nodosa is a rare condition of degeneration of the media, proliferation of the intima, often associated with thrombosis, and granulomatous periarteritis; the veins are also affected and the condition may be widespread in the body.

CHRONIC ARTERIAL DEGENERATIONS

Senile Degeneration (*Medial Degeneration*). In old age small foci of calcareous material may not uncommonly be found in the middle coat of arteries on the site of degenerated muscle cells. An extreme degree of this type of degeneration, however, is called *Mönckeberg's sclerosis*. It affects chiefly the larger arteries, especially the iliacs and femoral vessels, and occasionally also the lower part of the abdominal aorta, and may cause senile gangrene. The initial change appears to be a hyaline degeneration of the muscle and connective tissue

cells of the media. This degeneration is succeeded by the deposition of lime-salts in the degenerated bands of muscle tissue, so that, in the course of time, the middle coat comes to be replaced by more or less complete rings of calcareous material. The affected artery becomes, in consequence, more or less rigid and may be slightly dilated. Atheroma may be present in the intima, but there is no inflammatory reaction around the calcareous material.

It is essentially an arterial degeneration of old people, and must not be confused with the calcification that frequently occurs in the intima in relation to atheromatous *débris*.

Atheroma (*Athero-sclerosis, Nodular Sclerosis*). This condition was at one time called endarteritis deformans, but inasmuch as the initial change is primarily and sometimes solely a degenerative one, the term endarteritis is not now heard so often. The degeneration is essentially patchy in its distribution, though, in the smaller arteries, it may be more diffuse.

There is still considerable doubt regarding its pathogenesis, but probably the initial change is a local degeneration characterised by the appearance in the intima of cholesterol, fatty and lipid substances. Along with this, either as a result of irritation produced by the necrotic *débris* or as a compensatory measure, there frequently occurs a thickening of the intima over the degenerated focus, so that the latter comes to lie in the deepest part of the intima and contiguous to the media. The intimal proliferation and sclerosis may cease and the degenerative process may extend towards the lumen, in which case the intima may finally give way, and what is called an "atheromatous ulcer" forms. Very occasionally the media, where it is adjacent to the degenerated intima, may also undergo fatty degeneration, but it must be emphasised that this is merely an occasional and purely secondary occurrence. The degenerated area in the intima contains, as has been stated, cholesterol, fat, lipoids, etc. Some of these may become converted into soaps, and later calcification occurs, so that occasionally, especially in the lower part of the abdominal aorta, large calcareous plaques may be found. Hence in atheroma of the aorta we may see a variety of lesions.

Thus yellow patches marking the site of fatty deposits in the intima may co-exist with opaque whitish cushions, the result of fibrous thickening of the intima obscuring the fatty *débris* below them. Along with these we may see superficial erosions of the fattily degenerated intima (atheromatous ulcers) or calcareous plates frequently pigmented by the remains of broken-down erythrocytes and sometimes covered by a mural thrombus. Occasionally, where the media has been partly involved in the degenerative process the weakened wall may undergo some degree of stretching. Occasionally also a calcareous plate may crack across and so allow blood to force its way between the coats of the artery (dissecting aneurysm). There are, however, no puckered scars unless syphilitic mesaortitis happens also to be present. The difference in the naked-eye characters of the lesions depends on the relative proportions of lipid degeneration and of intimal sclerosis. In the aorta such patchy nodular thickenings may do relatively little harm, but in the case of the smaller arteries it is quite another matter. These small arteries show much the same type of lesion. It is essentially focal, but may be more diffuse. The nodular thickenings of the intima project into and deform the lumen, which readily becomes obliterated by thrombus formation, so leading to infarction. Where the media is secondarily involved irregular dilatation occurs and the vessel may rupture, especially in places such as the brain, where the vessel is poorly supported. The extent of arterial territory involved varies in different cases. Sometimes only the aorta is affected, sometimes only the smaller arteries or one particular group of such arteries—for example, the coronary, cerebral or renal.

This form of arterial degeneration is best seen in the older age periods, and is frequently a cause of death, but it may occur or begin at an earlier age. Mention may be made here of fatty deposits, often in the form of sheaths, which take place

in the connective tissue beneath the intima as a result of acute fevers. They have been called, probably incorrectly, "early atheroma."

Diffuse Hyperplastic Sclerosis (*Arterio-capillary Fibrosis*). This change, which is associated with increased arterial blood pressure, is usually met with in persons in the third to the fifth decades of life. The vessels affected are chiefly the small arteries and arterioles, and the initial change appears to be a tonic contraction of the media of these small arteries. Both the muscle and the elastic elements in the media undergo hypertrophy, but later they become atrophied and replaced by fibrous tissue laminae. Along with this there occurs a proliferation of the cellular elements in the intima, which thus becomes more or less uniformly thickened. There is also a new formation of elastic fibres in the thickened intima. In the smallest arterioles the chief change is the intimal one. The lumen of vessels of this calibre becomes much narrowed and may become completely obliterated, with the result that atrophic changes and fibrosis occur in that part of the organ supplied by the affected vessel. The thickened intima in affected arterioles undergoes sooner or later a hyaline change, and fatty degeneration may occur.

Diffuse hyperplastic sclerosis occurs most commonly in the kidneys and next in the spleen and other organs, including the brain, pancreas, liver, suprarenal glands, and less often the stomach and intestines, but not the heart or skeletal muscles. The increased peripheral resistance throws more work on the heart and the left side undergoes very considerable hypertrophy (concentric hypertrophy). This condition may exist without any noteworthy renal change, or the kidneys may show a certain amount of scarring and may even be granular. These renal changes, however, are merely atrophic, depending on the cutting off of the blood supply to areas of kidney tissue (*ischaemic atrophy*). This is a *primary* diffuse hyperplastic sclerosis.

Similar vascular changes, however, may occur *secondarily* in kidneys that are primarily the seat of chronic inflammatory changes, either of a diffuse or focal type, and will add their quota to the inflammatory damage. In these cases also the blood pressure is raised and the left heart hypertrophied. It would thus appear that, owing to a previous inflammatory affection of the kidneys, some substance or substances are retained in the blood and cause a tonic contraction of the small arteries and arterioles, in the kidneys and elsewhere. The same agent or some other irritant may also be responsible for provoking the other changes already described. However, the relations between the primary and secondary disease may be very close, since high blood pressure has been found to result from war nephritis, the nephritis itself having apparently disappeared.

ARTERIOSCLEROSIS

Arteriosclerosis means hardness of arteries. The word is often used in a restricted sense as synonymous with diffuse hyperplastic sclerosis; but it is convenient to have a term that can be used at the bedside to embrace all the various chronic arterial degenerations just described, since exact differentiation will often be impossible during life, and it is quite likely that they are all types of the same morbid process. It is in this wider sense that the term is used in this book.

Ætiology of Arteriosclerosis. It is possible that the different types are not so much due to different noxious agents as to the different soils in which the bacterial toxins or other agents are implanted. Thus in young people the inflammatory changes result in great internal proliferation (diffuse hyperplastic sclerosis) while in the elderly or cachectic such an intense reaction is impossible, and the blood pressure remains low (senile degeneration) (32). Allbutt has pointed out that there is no tendency for primary arterial changes, such as atheroma and senile degeneration, to cause high blood pressures. On the other hand, diffuse hyperplastic sclerosis is associated with a high blood pressure, so that, if all cases with hard arteries are grouped together under the term *arteriosclerosis*, in some the blood pressure will be normal, in others it will be raised. Arterio-

sclerosis, in particular atheroma, is not an uncommon degeneration in the arteries of those whose occupation exposes them to severe muscular strain, and, therefore, intermittent increase in blood pressure may be a pre-disposing factor. The various factors that play a part in the ætiology are over-eating in particular of protein and fatty foods—excess of milk has been incriminated (57), and blood pressure is lower in vegetarians (58) than meat eaters—gout, alcohol and lead poisoning, malaria and other acute infections, with their bacterial toxins, particularly typhoid, hypothyroidism, Bright's disease (see diffuse hyperplastic sclerosis) and possibly intestinal intoxication. Arteriosclerosis may be associated with diabetes in elderly people, owing to the protein and fat diet so commonly taken, but in other cases the diabetes may be secondary, owing to the failure of blood supply to the pancreas, because the vessels are sclerotic.

Pathology. The suggestion has been made that there is primary weakening both of the muscular and elastic elements of the arterial walls; they become stretched and dilated and anatomic alterations with calcification serve the purpose of strengthening the walls and take place particularly at points where there is special strain from the whirl of the blood stream—flexures and the places where arteries branch off. Calcification means healing and rupture never takes place at these points. Elsewhere in the arterial wall the process is diffuse. The rise of blood pressure is secondary (59).

Symptoms. In the earlier stages the artery is palpable, and can be rolled under the fingers when all the blood has been squeezed out of it by pressure from the fingers. The artery feels thick. In the later stages the wall may feel hard from calcification. The transverse diameter may be increased, and the vessel may become tortuous, owing to lengthening of the artery. Pulsation is often much diminished, and sometimes is absent altogether; thrombosis may occur. Since the velocity of the pulse wave increases with the rigidity of the artery, the determination of the former by means of the "hot wire" sphygmograph should indicate the amount of arteriosclerosis in a given case.

In arteriosclerosis the coronary arteries are very commonly atheromatous, so that the nutrition of the heart muscle is affected, leading to myocardial degeneration. Consequently symptoms of early cardiac failure may be present—exhaustion, breathlessness, and pain on exertion.

Arteriosclerosis may cause local symptoms from its presence in certain organs. In the brain it may lead to thrombosis or hæmorrhage, and reproduce the characteristic symptoms. Arterial spasm gives rise to a condition that in the presence of albuminuria resembles uræmia and has been called *pseudo-uræmia* (see p. 303).

Prevention and Treatment. Prophylaxis consists in treating the causes of the condition. Over-eating must be avoided. Improvement may take place even when the disease is established. Rest in bed for a period should be prescribed, since the horizontal position takes the strain off the circulation. Iodides are commonly given, and these may be beneficial if there is an element of hypothyroidism present, which is not uncommonly the case. Thyroid extract may also be tried. (See also Treatment of Arteriosclerotic Kidney.)

HIGH ARTERIAL PRESSURE

(*Hyperpiesia*)

The normal range of blood pressure in young, healthy adults is from 95 to 140 mm. (see p. 229). It has frequently been taught that the blood pressure increases with the age of the patient; in fact, formulæ relating age and blood pressure have been constructed. This view arises from faulty weighing of the evidence. There are many elderly people with perfectly normal arteries in whom the blood pressure is normal. On the other hand, arterial disease, which itself often leads to a rise of blood pressure or hyperpiesia, becomes increasingly prevalent as age advances, and this explains the fact that the average blood pressure of a group of

elderly people is found to be increased. In hyperpiesia values from 150 to 300 mm. and more have been recorded. The rise usually begins in middle life, *i.e.* above thirty, and is fully developed by the time old age comes on; so that it is at this period of life that it is most commonly met with; but it has been seen in infants, and even in the new-born. It affects males more than females. The ætiological factors described under arteriosclerosis may be responsible.

Pathology. Arterial pressure is within normal limits influenced by more than one factor; thus the pressure will be increased by over-action of the heart, by increased peripheral resistance, and by an increase in the viscosity (69) or volume of blood, though an increased volume is probably always a temporary condition. However, the main cause of hyperpiesia is an increase in the peripheral resistance, at first, perhaps, due to spasmodic contractions of certain arterioles; but later on in the fully established form it is due to swelling of an inflammatory character in the walls of the arterioles, which has already just been described under the heading *diffuse hyperplastic sclerosis (q.v.)*. The red cells and hæmoglobin of the blood are greatly increased in some cases (polycythæmia), and the high blood pressure in these cases may be partly secondary to the increased viscosity of the blood.

An investigation on a normal man, whose systolic blood pressure was actually below 100 mm., showed a rise of about 10 mm. through the day and a corresponding fall during the night. The rise was chiefly due to taking tea, coffee, and to smoking. Exercise, mental work, worry and excitement increased the rise, and alcohol diminished it. A marked rise was observed during a holiday in the Alps (34). This suggests that the lack of oxygen, due to the rarefaction of the air, stimulates the vasomotor centre. Experimentally, hyperpiesia has been induced in dogs by injecting certain colloidal preparations into the ventricular system of the brain; these clog up the Pacchionian bodies through which the C.S.F. is filtered off into the venous sinus; there is a permanent rise of C.S.F. pressure and a secondary rise of blood pressure (17). A pressor substance has been found in the urine in a young patient (68). The suggestion has been made that the liver is at fault in not destroying a toxin, since when the blood urea and non-protein nitrogen are normal, indicating unimpaired renal function, there is a raised amino acid, uric acid, and cholesterol content in the blood, there is more ammonia nitrogen in the urine compared to the urea nitrogen than normal (ratio under 1 to 30), and there is an increase of urinary indican (71).

Symptoms. In the early stages of the disease, at any rate, in some cases, the hyperpiesia is not constant, but occurs spasmodically. Later this condition is permanent. The patient may complain of headaches, insomnia, tinnitus aurium, and giddiness. Pain at the back of the neck near the occiput is very characteristic. The characteristics of high tension are: (1) the records on the instruments employed (*see Fig. 13B, p. 226*); (2) the sensation to the finger of a firm well-filled artery, with long-sustained systole, never completely empty during diastole, capable of being rolled under the finger, but not necessarily palpable as a thick structure when emptied by pressure of the finger; (3) the evidence of enlargement of the heart and forcible apex beat; (4) the modified heart sounds, lengthening and muffling of the first sound at the apex, and accentuation or ringing character of the second sound in the aortic area.

(5) Ophthalmoscopic examination often provides a valuable means of estimating the degree of arterial changes since it is possible to infer from the appearance of the retinal arteries what is the condition of the cerebral arteries. In an early stage the ophthalmoscopic changes are confined to the arteries. In general, the lumen is reduced in size when compared with the veins. The walls of the retinal arteries normally reflect the light to some extent, and this is seen as a bright streak along the middle of the vessel. In arteriosclerosis this reflection is increased owing to the thickness of the walls, and the smaller arteries appear burnished like *copper wire*, and later on, as the opacity of the wall increases,

they look bright like *silver wire*. This bright streak is often irregular and has a dotted appearance. The arteries are tortuous, but owing to extreme variability of the normal artery in this respect this feature is of no value in diagnosis; their lumen is irregular; they are often greatly reduced in size, sometimes looking like fibrous threads. Sometimes they are of normal width, but are sheathed in places by white plaque-like deposits which look like pieces of pipe stem; these may disappear after a time. Characteristic appearances are seen at the arterio-venous crossings. The line of the vein is displaced if it crosses the artery obliquely, so that it lies along the artery for a short distance on each side of the crossing. When the artery crosses in front of the vein, the latter seems to disappear at the crossing, because it becomes hidden behind the thick walls of the artery. The veins are pressed upon, so that there is a swelling of the vein on the distal side of the crossing, but this appearance, called "banking," is by no means very common (*see* Plate 14).

The retinal appearances (*arteriosclerotic retinitis*) are similar to those met with in chronic Bright's disease. Small flame-shaped areas may be seen, due to minute hæmorrhages in the nerve fibre layer; when present in the deeper layers of the retina the hæmorrhages are roughly circular. In a later stage there may be small bright spots with sharply defined edges scattered about, very often in the macular region, round which they may form a rough *star-figure*, or they may lie between the macula and the optic disc as a fan-shaped figure. They may be grouped round the radicals of the retinal veins, but more often they are scattered irregularly about. Often a large number are grouped together so closely as to resemble a piece of mosaic. Histologically these patches consist of round or oval masses of hyaline exudate in the internuclear layer of the retina. It is perhaps possible to regard them as of essentially the same nature as white infarcts due to blocking of the smaller branches of the retinal arteries.

Probably, in the majority of cases, the retinal changes persist until the patient's death; but improvement may take place, effused blood being absorbed, and even the spots of degeneration disappearing. In the earlier stages there is no loss of vision. Gradual impairment of vision may be due to degeneration of the nerve elements in the retina from defective blood supply. The fields of vision may become restricted. Optic atrophy may be seen and may be preceded by some slight swelling of the disc. Sudden temporary loss of vision (*amaurosis fugax*) has been attributed to spasm of the thickened retinal arteries (described later). Sudden permanent blindness, quite painless, may result from thrombosis of the central retinal artery. The retina appears pale; the macula shows up in contrast as a cherry-red spot. The blood column in the vessels is broken up into small blocks of red cells with intervening clear spaces of plasma (cattle-truck appearance).

Most of the other conditions found in these cases are not so much evidence of the high tension as the results of the circulatory difficulties which ultimately supervene in the worst instances. They are slight albuminuria, due to secondary renal involvement (*see* arteriosclerotic kidney, p. 532), though in most cases the blood urea is either not at all or only a little raised, and there is usually little or no impairment in the kidney function; hæmorrhages in different parts of the body, as, for instance, epistaxis, hæmoptysis, retinal and vitreous hæmorrhages, and possibly small cerebral hæmorrhages, bleeding from piles, angina pectoris, itching, cramps in the calves of the legs.

The *hypertensive cerebral attack* or *encephalopathy*, also called *pseudo-uræmia*, is rather characteristic. There is a rapid rise of blood pressure before the attack, which may be due to spasm of small cerebral arteries or sometimes to cerebral œdema. The symptoms are transient pareses of muscles, convulsions, aphasia, blindness, hallucinations, delirium, stupor and coma. This symptomatology is still further described under the heading *chronic cerebral softening*.

In many cases of primary hyperpiesia there is a high degree of congestion of

the surface blood vessels. Such persons with advancing years may have the appearance of robust health, from the rich colour of the face, and may seem to be only instances of the somewhat florid colour which so many healthy old persons present. Dieulafoy notes the increased sensibility to cold (*cryæsthesia*, κρύος, cold) which these patients suffer; there may be dead fingers or the cold is felt in the lower extremities, and drives the patient to wear thick clothing, even in the warm seasons. In a patient of the writer's, hyperpiesia led to gangrene of both lower limbs. These cases terminate eventually from an attack of coronary thrombosis or cerebral hæmorrhage, or failing heart, with dropsy and œdema of the lungs, and occasionally from uræmia—cases of so-called "malignant hypertension." In coronary thrombosis and cerebral hæmorrhage death may be sudden.

Treatment. If the cause of the high blood pressure can be recognised, attempts must be made to remove or reduce it. Where there is good reason to believe that the mode of life is contributing to the result, help may be sought by the avoidance of butcher's meat and highly nitrogenised foods or those containing purin bodies, by abstention from alcohol, tea, and tobacco, and from excessive mental or physical strains. It is advisable to give calomel (2 or 3 grains) or blue pill (3 to 5 grains) as an occasional purge, followed by a morning laxative saline. The blood pressure is often reduced promptly when the patient is compelled to take complete rest in bed. Vaso-dilators, like nitro-glycerine, amyl nitrite or sodium nitrite will be useful if angina occurs. Potassium iodide is commonly given; and massage, muscular exercises, high frequency currents, and hydrotherapy will sometimes be beneficial. Since the high blood pressure is probably compensatory to a lesion of the arteries or to chronic toxic nephritis, no attempt should be made to lower it by drugs. Digitalis is not suited for early stages, but may be helpful when the heart has reached an advanced stage of dilatation and there is œdema. The oxygen tent is useful in such cases. In cases of hyperpiesia with high hæmoglobin the question of venesection should be considered, especially if symptoms such as headache are present. Relief may be obtained by removing a pint of blood, and this may be repeated at intervals. Venesection may also be employed when there is failure of the heart. (*See also Arteriosclerotic Kidney.*)

INTERMITTENT CLAUDICATION

In this condition of intermittent limping or *claudication* the patient finds that after walking a certain distance he has weakness in one or other leg, with stiffness, heaviness, numbness, pricking sensations, pains and cramp, so that he necessarily limps in his gait. The painful sensations increase as he progresses, and he is at last obliged to stop. The foot or leg shows signs of circulatory disturbance; it becomes red, often with a cyanotic tinge, mottled, and swollen; and the toes may be white and "dead." After a period of rest the symptoms gradually subside.

The symptoms are due to the affected arteries being unable to carry the increased flow of blood that the limb requires during muscular exercise. In nearly all there is an absence of pulse in the dorsalis pedis artery, or in the posterior tibial of the affected limb (39). The blood pressure is sometimes high. In some cases slight muscular wasting and degeneration of the peripheral nerves (peripheral neuritis) have been observed. In many instances the complaint has resulted in dry gangrene of the limb, and it has been associated in a few cases with Raynaud's disease of the upper extremities. The cerebral vessels are sometimes affected with transient hemiplegia and other paralyses, blindness, headaches, and mental symptoms.

Ætiology. In the majority of cases there is evidence of sclerosis of arteries or veins, or of obliterative arteritis or atheroma, or thrombo-angiitis obliterans (*g.v.*) In such cases as do not present any evidence of arteriosclerosis or obliterative arteritis, it is assumed that the condition is due to arterial spasm. It is a disease of adult life; and gout, diabetes, and syphilis, and indulgence in

tobacco or alcohol are often among the antecedents. It is more common in men than in women.

Pathology. It has been shown that if some muscles of a limb are exercised, when the circulation to the limb has been stopped by a tight bandage, pain will be produced in those muscles, and the pain is due to some substance—the P factor—which is liberated from the active muscle into the surrounding tissue spaces and which disappears when the oxygen supply is increased.

Prognosis. Apart from the possible onset of gangrene or other results of arteriosclerosis, the disease is not dangerous. Relief from symptoms depends on the power of the artery to dilate; this may be tested by warming up another part of the body, *e.g.* by a hot-air bath over the trunk or plunging the whole of both upper extremities in a hot bath, when the normal reaction is a rise of the skin's temperature of the legs (72). No operative treatment should be undertaken unless this reaction is obtained.

Treatment. The patient must limit his exercise, and avoid quickening the circulation up to the point at which the obstruction in the vessel will begin to operate. Frequent rests in bed may be advisable. Iodide of potassium, sulfarsenol, etc., may be tried in syphilitic cases, and the local remedies used in Raynaud's disease may be employed here, also the constant current, electric baths, warm baths, high frequency currents, and gentle massage. Diathermy applied to the trunk has proved of value. Administration of CO₂, 5 to 7 per cent. with air, in the horizontal position, so as to cause deep breathing for fifteen minutes several times a week has been of benefit.

If gangrene occurs, the pain may be relieved by morphia, and the part should be amputated at a suitable opportunity. The condition of the arteries, *i.e.* the amount of calcification present, may be determined by radiography, and this will help in deciding whether amputation should be performed high up or low down. Gangrene and threatened gangrene have also been treated by removing the sympathetic nerves round the artery, so as to prevent arterial spasm and by injecting alcohol round the artery (40). Lumbar sympathectomy in thromboangiitis obliterans produced good results in nine out of sixteen cases (65).

ERYTHROMELALGIA

In this condition, first described by Weir Mitchell, there are attacks of acute pain in the feet and legs associated with, or followed by, dilatation of the blood vessels, the part becoming bright red or deep purple in colour, with shiny surface, prominent veins, and perhaps sweating. The upper limbs and trunk are also sometimes affected. The pain is acute, burning and throbbing. The attacks are brought on and aggravated by heat, exercise, and a dependent position of the limbs; and some relief is obtained by cold and by elevation of the limbs. The attacks last at first a few hours; but with the progress of time they are more persistent, and perhaps at the same time less severe. It occurs in men of early middle age, and rarely in children.

Two of Mitchell's cases subsequently developed spinal symptoms, and other cases have been seen to be associated with tabes, syringo-myelia, and disseminated sclerosis. Some cases of erythromelalgia appear to be due to ergotism and thromboangiitis obliterans. In the latter disease the erythromelalgia has been associated with intermittent claudications, and it has been suggested that it acts as a compensatory mechanism whereby the blood supply to the part is increased by dilatation of capillaries. Erythromelalgia has been observed in the arsenical poisoning of beer-drinkers.

The treatment is mainly symptomatic: by cold, suitable position, and the use of morphia. Faradism and massage have also been of use.

Acroparæsthesia.—In this there are disagreeable or painful sensations, tingling or numbness, or "pins and needles" in the hands and feet. It may be accom-

panied by vasomotor disturbances. It is more common in women than in men. The disagreeable sensations are felt usually in one or both arms when the patient wakes in the morning, and after a time the symptoms subside. Sometimes the hand is paler or redder than normal, or even swollen. In a few cases there appears to be a sufficient cause in much use of the hands in some occupation during the day, or in a faulty position of the arms during sleep; but often no cause can be discovered. The pathology is not clear: it has been attributed to vasomotor spasm, but in many cases there is no evidence of this. It has been seen in general paralysis, tabes dorsalis, and allied disorders; but as a rule it is independent both of these and of hysteria. The treatment consists of rest, tonics, potassium bromide at night, and the constant current.

ANEURYSM

This name (*ἀνεurύνω*, to widen) is applied to dilatation of an artery for a more or less limited extent of its course. Aneurysms are divided, according to their shape, into *fusiform* and *sacculated*, the fusiform being a more or less uniform dilatation of the whole circumference of the vessel; the sacculated forming a globular projection from one side of the vessel, and connected with it in advanced cases by a constriction or neck. Sometimes, especially in the limbs or the abdomen, a sacculated aneurysm ruptures at a prominent point; blood oozes slowly out into the tissue around and forms a coagulum, bounded by a kind of cyst of inflammatory tissue. This has been called a *diffused* aneurysm. Lastly, a *dissecting* aneurysm is formed when at a part of the artery affected with atheroma the blood penetrates the inner and middle coats, and forces its way between them and the outer coat.

Ætiology. Aneurysms arise from any cause that weakens the vessel at one point. A common cause is atheroma, especially in the large vessels, in which the inner and middle coats are weakened, and the whole wall yields to the pressure of the blood at that point. In smaller vessels, such as those of the brain and lungs, the vessel may be weakened by the local causes of arteritis already mentioned—viz. embolism or the invasion of tubercle. Surgical injuries of the outer coat also lead to aneurysm. Irritation is another predisposing cause, and accounted for the frequency of popliteal aneurysm in the old days, when horse-riding was more common than at present. Of the more general causes disposing to aneurysm syphilis holds an important place, and probably also excessive strain acting through the circulation.

Morbid Anatomy. The following description of results applies chiefly to the sacculated forms. One result is the *coagulation* of the blood in the sac itself. As this is out of the direct current, it moves more slowly, and its coagulation is favoured by the roughness of the aneurysmal sac. The sac thus becomes lined, or nearly filled, with successive layers of pale buff fibrinous deposits; and it is by the complete filling of the sac with these fibrinous layers that aneurysms may be obliterated and cured. The greater the freedom of communication with the main vessel, the less the liability to the formation of fibrin; and in a fusiform aneurysm no deposits take place.

Another result of aneurysm is its *pressure* upon the parts around it. The sac may attain an enormous size; an aneurysm, of which there is a model in the museum of Guy's Hospital, springing from the aortic arch, measured 8 inches in diameter.

A third effect of aneurysm is *hæmorrhage*, which is often the cause of death. Ruptures into hollow viscera and serous cavities are often rapidly fatal. Ruptures into connective tissue or intermuscular spaces are often much slower in their effects, and in the limbs may allow time for successful treatment.

Symptoms. They may be divided into those common to all aneurysms and those determined by the locality.

in twelve months, the average duration being increased by those cases where life is greatly prolonged. This applies to males and females. In the case of single aneurysms the duration of life increases with age ; but the reverse is true when the aneurysms are multiple (65).

Treatment. The treatment of aneurysm in the chest generally resolves itself into—(1) rest ; (2) restricted diet ; (3) the use of anodynes and sedatives ; (4) iodide of potassium. Absolute rest has been urged by some, the patient being in the recumbent position, and not allowed to sit or stand up for any reason whatever. However, the wisdom of such a course is very doubtful, especially as in many cases the myocardial changes ultimately cause death. However, it is very important to avoid excessive exercise. The diet which was recommended by Tufnell, who strongly advocated absolute rest, consisted per diem of 10 ounces of solid, including 3 of meat, and 8 ounces of fluid, divided into three meals ; but it is extremely trying, and few patients will submit to it. It is suggested that a high-protein diet will increase fibrin formation in the sac. Opium or morphia is generally given to ease pain, to produce sleep, or calm restlessness, but other sedatives may also be of use, such as bromide of potassium, chloral, paraldehyde, or sulphonal. Pain may also be relieved by belladonna applications, or by cold, or by venesection to a small amount. Iodide of potassium appears to have a special influence upon the coagulation of blood in aneurysms, as great improvement in diminution of pulsation and of pain has followed its use, even though unassisted by restriction of diet. It may be given in increasing doses, up to 60, 90, or 100 grains daily. Colt has devised a simple method of “ wiring ” an aneurysm. A trocar and cannula is introduced into the sac after anæsthetising the skin. If there is a free flow of blood a closed set of wires in a container is introduced through the cannula, and, on entering the sac, they open out in the form of an umbrella to induce clotting. A remarkable success has been reported by Theodore Thompson, but in two or three cases the writer has found that no blood issues from the sac in spite of there being well-marked expansile pulsation.

ABDOMINAL ANEURYSM

Pathology. The usual seat is between the diaphragm and the origin of the superior mesenteric artery, and it often involves the origin of the cœliac axis. In its growth it may interfere with adjacent organs, press upon the vena cava, or erode the vertebræ. Aneurysms of the superior mesenteric, or of the iliac arteries, are less common, and will not be specially considered here.

Symptoms. These are pain, the presence of a pulsating tumour with murmur, and sometimes evidences of pressure. The *pain* is situate in the abdomen, is often severe, paroxysmal or neuralgic in character, and may radiate to either side, into the groin or the back. The *tumour* varies with the seat of the lesion ; it is more common in the epigastric region, in the middle line or slightly to the left ; it is globular or ovoid, pulsatile, and expansile ; it is scarcely, if at all, affected by the movements of the diaphragm. A systolic murmur can generally be heard over it. The pressure signs other than pain are not common, since the several organs readily yield to its progress. The average age of onset is thirty-six years in males, and the average duration is eighteen months, the median being thirteen months. Death may result from rupture of the sac into the retro-peritoneal tissue, into the peritoneum, or into one of the hollow viscera.

Diagnosis. It is very common to feel a pulsation of the normal aorta in women on palpating the abdomen, particularly if the muscles of the abdominal wall are weak. This is often mistaken for abdominal aneurysm by the inexperienced. Abdominal aneurysm must also be distinguished from tumours lying in front of the aorta, especially *carcinoma of the stomach*, or less commonly cancer about the *gall bladder*, to which pulsation is communicated from the

healthy aorta. Tumours over the aorta do not expand laterally, and are often irregular or nodulated in shape; the pulsation in some cases ceases when the patient is placed prone, or on his hands and knees, so that the tumour may fall away from the aorta. Carcinoma of the stomach is displaced more than an aneurysm by a deep inspiration.

Treatment. This must follow the lines indicated under the head of Thoracic Aneurysm. But an abdominal aneurysm is sometimes open to treatment by proximal or distal compression by the tourniquet. Colt's wires may be introduced during laparotomy.

CONGENITAL COARCTATION OF THE AORTA

In this condition, which is rare because it is rarely diagnosed, there is stenosis or complete obliteration of the aorta at the point of junction with the ductus arteriosus just beyond the origin of the left subclavian artery. If the child survives, the circulation to the lower limbs is helped by anastomosis between branches of the subclavian and axillary arteries on the one hand and the thoracic arteries and epigastric arteries on the other. The anastomosing arteries become enormously enlarged to carry the necessary amount of blood, and they form large tortuous pulsating vessels which can be felt, especially along the dorsal border and at the angle of the scapula and also elsewhere. There is high blood pressure and hypertrophy of the heart, which forces the blood through the narrow opening; there is no dilatation. X-ray shows depressions along the rib margins from pressure by the dilated arterial anastomoses. There may be systolic murmurs, laterally to the sternum from dilated mammary arteries. The abdominal aorta and iliac and femoral vessels may be devoid of pulsation, or pulsate but feebly, from the diminution of the force of the current by the time the blood reaches them through the narrow aorta; the difference between the blood pressure in the brachials and femorals is a valuable diagnostic point. The condition is compatible with a life of hard muscular work; sudden heart failure is prone to occur. The **diagnosis** depends on palpating the femoral arteries in all young subjects with persistent high blood pressure and feeling for anastomoses round the scapulæ (61).

RAYNAUD'S DISEASE

This disorder, first described by M. Raynaud in 1862 as local asphyxia and symmetrical gangrene of the extremities, is due to a spasmodic local contraction of the smaller arteries, commonly the digital arteries, whereby the circulation in the affected parts is retarded or arrested. Up to the present time Raynaud's disease has been thought to be due to vasomotor spasm, and relief in varying degree has been brought about by resection of certain parts of the sympathetic chain. Such spasm is presumably secondary to intestinal stasis, which is almost invariably present, and the symptoms can be removed by lavage of the intestines by an Einhorn's duodenal tube. Further, people with chronic constipation often suffer from cold hands and feet. From recent observations, however, it is claimed that the arteries are directly affected and that the vasomotor system plays only a secondary rôle (16), though doubt has again been cast on this (70).

Ætiology. It is much more frequent in women than in men, and is first noticed commonly between the ages of fifteen and thirty, or even in childhood. Cold and emotional disturbance are exciting causes. Many patients are delicate or anæmic, nervous or hysterical, but some seem to have been in good health until the occurrence of the disease. Associated with Raynaud's disease, hæmoglobinuria, peripheral neuritis, and various skin eruptions, particularly scleroderma or sclerodactylia, have occurred. In the latter condition the skin of the fingers becomes thick, smooth and glossy, and eventually atrophies.

Symptoms. During the attack, which may be due to cold or emotion or begin spontaneously, one or more fingers turn cold, numb and painful. The colour is either white (*local syncope*) or bluish-white, violet, slate-coloured, or even black (*local asphyxia*). When the fingers are blue, pressure produces a white spot, which only slowly regains the former livid colour. The adjacent part of the extremity is often slightly swollen, and there is a livid marbling of the limb for some distance above it. The condition lasts from a few minutes to several hours. Recovery is accompanied by tingling and pricking, and the livid tint gradually passes through scarlet to the natural pink colour. During the height of the attack the arterial supply is entirely arrested, so that the shade of blue depends on the amount of blood remaining in the capillaries and venules. The "dead fingers" that occur in many normal people after exposure (*e.g.* prolonged bathing) and sometimes lead on to frost bite are not examples of Raynaud's disease.

The severest stage is the condition known as *symmetrical gangrene*. During an attack, such as has been described, vesicles or bullæ containing sero-purulent fluid form on the fingers and burst, leaving small ulcers, which heal after the lividity subsides. With a repetition of this process, numerous small cicatrices may form on the affected part, and the fingers acquire a shrivelled, pinched, parchment-like aspect. The skin may desquamate, and the nails may fall off. In other cases, without the formation of bullæ or phlyctenulæ, the fingers and toes become black, shrivelled, and gangrenous; and then a superficial layer of skin, or even some portion of the deeper tissues, separates as a slough in the course of a few weeks. The most marked symptom accompanying these severe cases is intense pain, of paroxysmal character, radiating to other limbs; the pulse may be thin or compressible, but is always perceptible, and the general health of the patient may be remarkably little affected. The toes are attacked as well as the fingers, and sometimes before them; and the nose and ears may be livid, but do not often slough. When the ulcers heal, it is remarkable what slight scarring remains behind.

The attacks occur at intervals of weeks or months, and in some cases, after repeated slight attacks, the fingers remain in a permanently benumbed or shrivelled condition.

Diagnosis. Senile gangrene is distinguished by the age of the patient, by the gangrene affecting a single limb, and generally a lower limb, by its progressive course, and by the diseased condition of the artery of the limb. *Chilblains* present a certain resemblance to local asphyxia, and perhaps may have an allied pathology; they occur from definite exposure to cold.

Prognosis. The disease is not mortal. Much good may be done with treatment.

An efficient **Treatment** of Raynaud's disease consists in irrigating, at periodical intervals, the intestines with 4-6 pints of a 0.85 per cent. solution of sterile saline at body temperature through a duodenal tube, the object being to wash out the contents of the alimentary canal. Alternatively, from 1-2 pints of the solution may be drunk each morning. Intravenous injections of radium emanation in normal saline has also been advocated by Tominek (Prague). Local measures consist in keeping the hands and feet warm; friction, which may be combined with hydrological methods, such as alternative hot and cold douches; high frequency and diathermy. The most valuable drugs are iodine and thyroid. It may be advisable to remove the patient to a warm climate in winter.

PHLEBITIS

Inflammation of the veins, or phlebitis, results in thickening and infiltration of the walls with leucocytes, which may be in such numbers as to constitute a real suppuration of the coats. The terms *endophlebitis* and *periphlebitis* have been

used to indicate inflammation of the intima and the adventitia respectively. Periphlebitis arises from contact with inflammatory foci outside the vein, or from injury. Endophlebitis is most often set up as a result of thrombosis or coagulation of blood in the vein itself. This occurs from a variety of causes (*see* Thrombosis). The clot may then adhere to the vein wall, becoming at the same time organised, and the vein may be completely obliterated. On the other hand, the clot may become channelled, and allow the continuation of the circulation; or in other cases it softens down into a puriform liquid. Periphlebitis extending inwards itself leads to thrombosis; on the other hand, abscesses may form in the tissue around the vein. *Thrombophlebitis migrans* is a condition which has been diagnosed more frequently of recent years, in which veins in various parts of the body are attacked, including the viscera; the lesions probably arise from a septic focus. (For literature *see* 64.)

Symptoms. Phlebitis is accompanied by pain and tenderness in the course of the affected vessel, with some reddening of the surface in the case of superficial veins. The vein can be felt as a prominent hard cord, and a varying amount of febrile reaction accompanies the local disease. The formation of abscesses will be indicated by hardening of the surrounding tissue, redness and œdema of the skin, and subsequently fluctuation. The secondary effects which result from breaking down, and transportation of the particles of thrombus, are described below.

The **Treatment** of phlebitis consists in complete rest of the part affected, the application of warm fomentations or of glycerine and belladonna to ease pain, and the administration of opiates, if necessary, for the same purpose. The risk of detachment of a thrombus must always be borne in mind (*see* Thrombosis and Embolism). If abscesses form the pus will have to be evacuated by incision.

THROMBOSIS AND EMBOLISM

Thrombosis is the name applied to the coagulation of blood within living vessels, whether arteries or veins, or in the cavities of the heart; and the clot itself is called a *thrombus*.

Embolism means the transference of a portion of clot or other substance (particles of tumour, parasites, fat globules) from one part of the circulation to another, and its impaction when it arrives at a vessel too narrow for its further progress. Embolism may take place along the arteries to the periphery of the systemic circulation, along the systemic veins and pulmonary artery to the lungs, and along the portal vein to the liver. The transferred particle is called an *embolus*.

Besides the conditions of fibrin formation which usually determine coagulation, two important factors in *thrombosis* are—(1) undue slowness of the current of the blood, whether from diminished cardiac force, from local obstruction in the vessel, or from increased viscosity of the blood, and (2) some lesion of, or irregularity on, the lining membrane of the vessel or cavity concerned; but it must be allowed that there is often an intimate relation with infective disorders in which micro-organisms or toxins may have a share, and with the conditions of health present in gout and in the puerperal state.

Thus we see that blood coagulates in the heart upon its inflamed valves, or in its cavities when dilated or contracting with extreme feebleness. It coagulates in the vessels if their walls are injured, or are in connection with septic or gangrenous processes; in the arteries especially when their walls are the subject of syphilitic or atheromatous lesions, or of aneurysmal dilatations; in the veins when the current of their blood is slowed by pressure, and with the slightest local disturbance in the subjects of various infective, cachectic, and anæmic disorders. The first step in the process seems often to be the accumulation of blood platelets

pain is not relieved by amyl nitrite nor even always by $\frac{1}{2}$ grain of morphia. The former should not be given owing to its stimulating effect on the heart. Later congestive heart failure may occur with œdema of the lungs. While this is a typical history it should be emphasised that the symptomatology is not constant. The attack may begin with fainting; there may be no pain. There may be sudden death. Coagulation of blood commonly takes place on the endocardium internal to the infarcted area and this may break off and cause embolism elsewhere (35). The patient may or may not have suffered from angina pectoris at the time, and if he recovers may later begin to suffer from angina, presumably owing to the extra work thrown on the remaining healthy cardiac fibres. The patient may live for hours, days and even years, remaining capable of active work. John Hunter, who probably had a coronary thrombosis at forty-five, lived for twenty years (36). Immediate absolute rest and oxygen constitute the treatment. The oxygen tent is most successful, and may relieve pain. The differential diagnosis from angina has been dealt with.

Femoral Thrombosis. Thrombosis of the femoral vein arises in the last stage of phthisis, cancer, and other exhausting diseases, in convalescence from typhoid fever and influenza, and after confinement ("white leg"). The leg becomes swollen, and the vein can be felt to be obstructed; there is generally also some tenderness from co-existing phlebitis. The detachment of a portion of clot, followed by its impaction in a large branch of the pulmonary artery with sudden death, is an occasional accident. To prevent thrombosis in the limbs during convalescence from fevers the movements of the patient must be regulated with care. He must not be allowed to lie so that the veins are compressed. Support can be obtained with soft pillows.

Jugular thrombosis and *thrombosis of the lateral sinus* result from the disease of the internal ear, or mastoid cells. From contact with the external ear, septic organisms are frequently present, severe phlebitis is set up, and the clot becomes septic. Particles are then conveyed through the right side of the heart to the lungs, in which pyæmic abscesses are formed. Other cerebral sinuses (longitudinal and cavernous) are sometimes thrombosed as a result of more general conditions, such as marasmus in infants, and chlorosis and anæmia in adults.

Thrombosis of the *pelvic veins* arises from disease of the pelvic viscera in women, or from gonorrhœa in both sexes. (See also Thrombo-phlebitis Migrans).

Thrombosis of the inferior vena cava is not incompatible with life. In one case who lived for twenty-five years, the vein was converted into an impervious ribbon from below the entrance of the hepatic veins. Blood was returned from the kidneys by way of the capsule and the lumbar and azygos veins. There is always great varicosity of the veins of the leg and abdominal wall, with a tendency to thrombo-phlebitis, hæmorrhoids, and varicose ulcers. The causes are infection, traumatism and malignant disease (37).

Large clots sometimes form in the *heart*, just previous to death, when the circulation is failing, and in recesses of the walls in cases of dilatation. They may hasten death by hampering the action of the organ, or they may supply emboli to the pulmonary or systemic circulation.

Embolism and thrombosis of the *cerebral arteries* are described under Diseases of the Brain.

Embolism of a large *artery* in a *limb* is not a very common event. It causes sudden acute pain, followed at once by numbness, coldness, and loss of power in the limb; the pulse is imperceptible below the seat of embolism, and, as already stated, gangrene may result. In the *spleen* and *kidneys* the occurrence of embolism is not so commonly recognised. Sometimes there is sharp pain in the left side from embolism of the spleen. Embolism of the kidney causes hæmaturia and frequently albuminuria too, and in malignant endocarditis there is often a condition of focal embolic nephritis present. Cases of embolism of the *mesenteric artery* have occurred in which the patient has been seized with severe

abdominal pain and distension, followed by collapse and death in one or two days ; and blood has been found in the bowel and in the peritoneal cavity. Very similar results may follow thrombosis of this vein, but the symptoms are more slowly developed.

The effects of embolism and thrombosis of the vessels of the *liver* are described under Pylephlebitis. Pulmonary embolism and thrombosis, and infarction and fat embolism are described on p. 177.

Embolism of particles of *new growth* is the cause of fresh growths in remote parts.

Treatment. The pain of embolism may be relieved by local anodyne applications ; if the large artery of a limb is obstructed, the limb should be wrapped in cotton wool or oiled lint. Embolectomy may be carried out during the first few hours or the clot may be manipulated into a smaller arterial branch.

ANGEIO-NEUROTIC ŒDEMA

This is an affection apparently connected with the vasomotor apparatus and closely allied to urticaria ; but the lesions are larger. Circumscribed swellings appear in various parts of the body—for instance, on the face, the eyelids, the hands or legs, in the throat or in the tongue. They are not inflammatory, and not dependent upon gravity ; they are not painful, but may be accompanied by burning, pricking and itching. They appear suddenly, last from two to six hours or more, and recur frequently, even daily ; on the skin they are generally harmless, but œdema of the larynx has frequently proved fatal. Gastro-intestinal symptoms are usually present, such as colic, nausea, and vomiting, and are attributable to an acute œdema of the gastric or intestinal mucous membrane. The disease is often hereditary, occurring in several members of the same family in two or three generations. It is one of the allergic diseases, like asthma (*see* p. 138), and is due to sensitisation to a foreign protein.

Treatment consists in finding out and avoiding the particular protein to which the individual is sensitive ; septic foci must be eradicated. Quinine, nitroglycerine and thyroid extract have given relief in a few cases. Laryngeal œdema may require intubation or tracheotomy

Mitroy's Disease.—This is a chronic œdema of both legs, often of familial origin, with a tendency to hyperplasia of the skin and subcutaneous tissue, of unknown origin.

DISEASES OF THE ORGANS OF DIGESTION

EXAMINATION OF THE ABDOMEN

THE abdomen is accessible to the same methods of examination as are employed in the case of the lungs and heart—namely, inspection, palpation, percussion, and auscultation; and in most instances it is desirable that the patient should be in the recumbent position, with the head rested.

For descriptive purposes the abdomen is divided into nine areas by means of two horizontal and two vertical lines. The vertical lines are drawn upwards from the mid-point of Poupart's ligament on each side to the costal margin. The horizontal lines are drawn across from the lowest parts of the costal margin, *i.e.* the tenth costal cartilages on each side, and between the highest points of the iliac crests. The names given to the regions mapped out by these lines are in descending order—(1) in the middle, epigastric, umbilical and hypogastric; (2) at the sides, hypochondriac, lumbar and iliac. As in the chest, accurate localisation of a lesion requires measurement from easily recognised parts, like the umbilicus, xiphisternum, middle line, pubes, anterior superior iliac spine, or tip of the eleventh rib.

Inspection. The first thing to notice is the size of the abdomen. This is extremely variable even within the limits of health. It may be uniformly much enlarged; but it requires the help of other methods of examination to determine whether this is due to a collection of liquid in the peritoneal cavity (*ascites*), to gas in the intestines (*meteorism*, *tympanites*), to fat in the parietes and omentum, or to some tumour, such as an ovarian cyst. Uniform and symmetrical retraction of the abdomen is seen in starvation, in emaciating diseases, and in death from cerebral diseases, such as tuberculous meningitis and intracranial tumour.

By inspection may be observed various local enlargements or prominences, such as result from tumours or enlargements of different organs, *e.g.* tumours of the liver, dilated stomach, distended intestines in cases of obstruction, infiltrated omentum and adherent intestines in tuberculous peritonitis, enlarged spleen, hydronephrosis, the pregnant uterus, ovarian and other cysts, and a distended bladder. Local enlargements in the upper part of the abdomen may cause asymmetry of the thorax by driving upwards and outwards the lower ribs on one side, thus enlarging the angle between the costal margin and the middle line. This is especially seen in cases of hydatid, carcinoma, and abscess of the liver.

It is important to note the relation of the abdomen to the respiratory movements already referred to in connection with the chest; the descent of the diaphragm is impeded by much distension, and is checked by acute inflammation of the peritoneum, so that in these cases respiration is almost entirely thoracic. In other cases respiration affects materially the position of the organs in immediate contact with the diaphragm, namely, the liver, spleen, stomach, and kidneys, whereas organs or tumours situated lower down, or connected with the posterior wall of the abdomen, are much less influenced by the descent of this muscle. The pulsations of the aorta, or of the right ventricle, or of the enlarged liver in tricuspid regurgitation, or very occasionally of an aneurysm, and the peristaltic movements of a dilated stomach or of the intestines, may sometimes be seen, the latter being visible in proportion to the thinness of the abdominal parietes and the vigour of the peristalsis.

Palpation. For this method of examining the condition of the abdomen,

the abdominal walls should be relaxed as much as possible, and hence the patient should be in the recumbent or semi-recumbent position, and the head should be supported, for if the patient raises his head—*e.g.* to see what is going on—the recti abdominis become tense. The relaxation of the abdominal walls is sometimes assisted by raising the patient's legs a little, but they must be supported in that position by a pillow under the knees. When the abdominal muscles are persistently tense, the patient should be asked to breathe deeply in and out, and should be engaged in conversation while the hand is on the abdomen, or he may be asked to lift up his head from the pillow, and keep it raised for about a minute, when the muscles will become exhausted, and for a moment afterwards the abdomen may be lax enough for the purpose. Another plan which has been recommended is to palpate the abdomen, when the patient is in a warm bath. If these means fail, and an examination is of the first importance, an anæsthetic should be administered.

The examination of the abdomen should be made with great gentleness; the hands should be warm, and should be laid flat upon the surface, and care should be taken not to force the finger tips suddenly into the abdomen, whereby the muscles are made to contract, and trustworthy results are impossible. During the movements of deep breathing enlargements of organs or new growths, especially in the upper part of the abdomen, may be detected, which would otherwise perhaps escape recognition. When examining the sides of the abdomen the observer should never neglect to employ the *bimanual* method—that is, one hand should be placed under the twelfth rib, and another on the abdomen in front; if one hand be pressed towards the other which is still, the slightest enlargement or resistance can generally be appreciated. In particular cases it may be desirable to examine the patient in the knee-elbow position.

In the normal abdomen there is scarcely any resistance to the movement of the hand in all directions. The solid organs, liver, spleen, and kidneys are almost entirely within the bony thorax; the left lobe of the liver, which lies across the epigastrium, is of small bulk, thin, and soft; the hollow viscera yield readily to the hand, and often nothing can be recognised, except, in thin people, pulsation of the aorta or iliac vessels.

By palpation in disease we can recognise changes in shape or size of the organs and the existence of tumours, and can obtain information on the following points: The condition of tenseness or relaxation of the abdominal wall, which may be local or general. The presence of tenderness, general or local; this may be elicited directly the hand touches the abdomen, or only when deep pressure is made. Various kinds of movement may be felt in the abdomen—the pulsations of the normal vessels, or of an aneurysm, or of the liver in heart disease; the peristaltic movement of the bowel; the movements of air in the intestine (*borborygmi*); the coarser movements or splashing of air and liquid in a dilated stomach when somewhat sudden pressure is made upon it; and the friction of inflamed peritoneal surfaces.

Under palpation also must be included two of the methods by which ascites or liquid in the peritoneal cavity may be recognised—namely, *fluctuation* and *displacement* (see Ascites).

Percussion. It is in reference to percussion especially that we must remember that the abdominal cavity extends up into the lower parts of the bony thorax. In health the abdomen is resonant over so much of the combined surfaces as corresponds to the intestines and to the stomach—that is, all the parts below the ribs, and the costal cartilages and lower ends of the ribs on the left side below the heart. It is dull over the parts which correspond to the liver and spleen—that is, for the liver the ribs of the right side below the upper border of the sixth in front, and the eighth at the side, and for the spleen the ninth, tenth, and eleventh ribs on the left side just behind the anterior axillary line. The relative areas of dulness and resonance may be much altered by changes in the amount

of gas in the hollow viscera, and the dull areas of the liver and spleen are moved downwards in inspiration and upwards in expiration. There is, further, much difference in the quality of the percussion note over the stomach and different parts of the intestine.

Alterations in the size of the liver and spleen, or the existence of solid tumours or cysts, will give rise to new areas of dulness, and such dulness will, as a rule, be accompanied by resistance appreciable by palpation. As constant reference to these altered conditions will be made under the diseases of the different organs, it is not necessary to specify them here. In percussion also we have another valuable method of recognising ascites (*q.v.*).

Auscultation. Friction sounds are occasionally heard over the liver and elsewhere in peritonitis; abdominal aneurysms may be accompanied by murmurs. If the region over the cæcum is auscultated, sounds are heard at intervals due to the passage of intestinal contents through the ileo-cæcal valve. In acute inflammation the movements stop, so that auscultation may be of value in suspected acute appendicitis.

Examination by X-rays. The œsophagus, stomach and alimentary canal are examined by giving the patient a meal mixed up with some salt opaque to the X-rays, such as barium sulphate or bismuth carbonate or oxychloride. Full details are given under the respective organs. For the examination of the colon an opaque enema may also be used. Other organs may be examined by taking plates of the abdomen after the alimentary canal has been emptied as far as possible by laxatives. In this way the presence of gall stones may be determined in favourable circumstances. Graham's method of demonstrating the gall bladder is described later.

Cœlioscopy. In this method a small incision is made through the abdominal wall under novocaine anæsthesia; air is passed into the peritoneal cavity and the contents viewed by means of a laparoscope. This method may be used purely for diagnostic purposes when an exploratory laparotomy would be unjustifiable (1).

THE ACUTE ABDOMEN

In view of the favourable results obtained from surgical intervention in many acute abdominal conditions the importance of diagnosis cannot be exaggerated. While the distinguishing marks of the various acute conditions are dealt with later under the various diseases, it has been thought advisable to give here some points about the examination of the patient and a list of the conditions that may give rise to the acute abdomen or to symptoms that resemble it.

The previous history will indicate not only whether similar attacks have occurred before, but whether there have been any suggestive symptoms, *e.g.* a history of dyspepsia, which may precede a perforated peptic ulcer or acute appendicitis. The menstrual history and the previous occurrence of jaundice, hæmatemesis, hæmaturia must be inquired into, and whether there has been recent loss of weight. The history of the present condition would include questions as to whether the onset of the attack was acute or gradual; the situation and the character of the pain; whether it has moved or shoots in a particular direction; whether there is any association of the pain with vomiting; the character of the vomit; whether there is nausea; the condition of the bowels. The examination must be complete—not only concerned with the alimentary system—so as to diagnose intrathoracic lesions, such as pleuro-pneumonia, pericarditis, and acute congestive heart failure with coronary thrombosis, the gastric crises of tabes and lesions of the kidneys and urinary tract, *i.e.* pyelonephritis, peri-nephritis, acute osteomyelitis and Pott's disease of the spine, and toxic conditions, *i.e.* uræmia, diabetic coma and cyclical vomiting. The colics may produce very acute abdominal symptoms, *i.e.* intestinal colic, lead colic, biliary colic, renal colic including oxaluria. Then there are the organic

intra-abdominal conditions, *i.e.* appendicitis, perforated peptic ulcer, and occasionally perforated intestinal ulcer; acute intestinal obstruction with and without strangulation, acute cholecystitis, diverticulitis, hæmorrhagic pancreatitis, pneumococcal and secondary peritonitis; ectopic gestation, salpingitis, and other gynæcological states; mesenteric embolism and thrombosis, Henoch's purpura and other intra-abdominal hæmorrhages and dissecting aortic aneurysm.

Other possible conditions are abdominal influenza, tuberculosis, especially of the ileo-cæcal glands, the enteric fevers, food poisoning, suppurative pylephlebitis, and, in the tropics, amœbic dysentery, hepatitis and malaria.

STOMATITIS

Inflammation of the mouth, or *stomatitis*, occurs as a general catarrhal condition involving the cheeks, gums, tongue, and lips, and in more localised forms, as aphthous, ulcerative, and gangrenous stomatitis, which are almost certainly due to micro-organisms. At the same time it is clear that some special conditions are required for the operation of micro-organisms, since the mouths of healthy persons contain innumerable micro-organisms, among which are staphylococci, streptococci, torulæ, and sometimes pneumococci, and diphtheria bacilli. The lesions of some diseases of the skin may involve also the buccalmucous membrane, such as those of herpes, pemphigus, and urticaria. *Herpetic stomatitis* is a condition in which numerous small ulcers occur over all the gums and inside of the cheeks; the ulcers are so tender that food must be fluid or semi-solid, as mastication is impossible. Treatment is by frequent application of glyc. boracis.

Stomatitis limited to the gums is called *gingivitis*. Different forms of gingivitis are seen in scurvy and in acute leukæmia, and as local results of dental diseases in the form of *pyorrhœa alveolaris*. For prevention of dental caries, see Vitamin D.

Oral Sepsis. It is necessary to lay especial stress upon the importance of a healthy condition of the teeth in relation, not only to stomatitis, but to conditions of general ill-health. Apart from acute alveolar abscess there are three conditions which are important from the medical point of view: (1) *Apical granuloma*, often incorrectly called abscess, which forms round diseased stumps and the roots of dead teeth and teeth which have become devitalised; these are always infected with streptococci, usually non-hæmolytic in type. As the granuloma has a thick wall and comes away with the tooth in extraction there is not so much danger of dissemination through the body as in rarifying osteitis, described later (2). There may be symptoms of general ill-health with fatigue and anæmia. It is probable that many diseases of obscure origin may in the future be traced to this cause. In particular, angina pectoris, rheumatoid arthritis, infective endocarditis, recurring gastric and duodenal ulcer, ocular inflammations, *i.e.* iritis, keratitis, choroiditis, may result from apical granuloma. Obviously dead teeth must be removed; but this is not enough, as a granuloma may be present when the tooth looks healthy, and there may be no pain and no tenderness on tapping the tooth. The only safe way is to take dental radiograms, when the granuloma is easily identified by the clear space at the root (*see* Plate 16); the root itself may become absorbed. These clear spaces due to infection must be distinguished from certain anatomical features, such as, in the upper jaw, the palatine fossa between the apices of the central incisors, and the nasal fossæ above, the maxillary antrum which is close to the roots of the molars and premolars in the lower jaw, the line of the inferior dental canal below the apices of the molar teeth and the mental foramen below the premolars. (2) *Pyorrhœa alveolaris*, where there is chronic inflammation with absorption of the bone surrounding the roots of the teeth. This begins as a thickening of the periodontal membrane—the clear area immediately surrounding the root—which may be localised at the gum margin or it may be general all round the root. The lamina dura—the opaque line

bordering the periodontal membrane—disappears. Pockets are formed between the teeth; the floor of the pocket is relatively wide between the roots of the teeth, while the opening of the pocket is constricted, so that it becomes filled with food *débris* and pus (*see* Plate 16). In proportion as drainage is restricted, infection by the blood stream is apt to occur; when there is a free discharge of pus, the micro-organisms may be swallowed and produce various alimentary disturbances. However, blood stream infection is probably more dangerous than swallowing the organisms. According to Goodrich and Moseley, pyorrhœa is due primarily to the leptothrix of the mouth; but other organisms, streptococci, etc., are always associated with it, and are responsible for the various diseases secondary to pyorrhœa. There may be rarefying osteitis with absorption of the apices of live teeth, or sclerosing osteitis, which makes the bone of the alveolus denser than usual at the apex of the tooth, which may become bulbous (3). Rarefying osteitis is also due to streptococcal infection, mostly non-hæmolytic, and dissemination *viâ* the blood stream takes place more readily than with apical granuloma (2).

The *prevention* of oral sepsis consists in keeping the teeth scrupulously clean and free from tartar. At the same time the greatest care should be taken that the gum is not injured habitually by too hard brushing. The diet should contain enough vitamins. The treatment of apical granuloma usually consists in the removal of the tooth, and the same applies to well-advanced pyorrhœa, as there is no cure for this condition. It is advisable to scale and otherwise clean up all the teeth on two separate occasions some days beforehand, as this will tend to prevent septic absorption. Then it is best to remove as far as possible all the condemned teeth at one time (4). Palliative treatment consisting in cleaning out the pockets periodically is also adopted.

A solution of thymol in water is a valuable mouth wash, as it is a particularly powerful antiseptic. Thymol is very slightly soluble in water, so that it is only necessary to put two or three crystals into a bottle of water and leave it to stand for some time. If the external temperature is high, the solution becomes stronger, and causes a stinging sensation in the mouth, and so it must be diluted before use.

CATARRHAL STOMATITIS

Ætiology. Catarrhal stomatitis may be set up firstly by chemical or mechanical irritation, such as contact with acids or alkalis, excessive drinking, or the presence of broken or carious teeth; secondly, by inflammation spreading from adjacent parts, such as the nose or naso-pharynx; thirdly, by the action of some poisons, viz. mercury, lead, and arsenic; and fourthly, in consequence of some general and mostly infectious conditions, such as measles, variola, syphilis, scurvy, leukæmia, and others.

Symptoms. These are swelling and increased redness of the mucous membranes of the gums, lips, and cheeks, swelling of the tongue, salivation and increased secretion of buccal mucus, which adheres as a coating to the surface, and swelling of the neighbouring lymphatic glands. Mastication and deglutition are painful, and the breath may be offensive. In later stages abrasion and superficial ulceration take place.

Treatment. All causes of irritation should be as far as possible removed; and antiseptic washes should be employed, such as boric acid (2 to 5 per cent.); potassium chlorate (3 per cent.): in later stages much more astringent solutions such as alum (5 grains to the ounce) or glycerine of tannin.

APHTHOUS STOMATITIS

This occurs in children, especially about the time of the first dentition, and less frequently in adults: it consists in the formation of circular grey patches, or

aphthæ, on the gums, tongue, and the inside of the lips and cheeks. They are from 3 to 5 mm. in diameter, slightly raised above the surface, and, though looking like vesicles, are really caused by a fibrinous exudation beneath the epithelium. After a time the epithelium is shed, and small ash-grey ulcers with narrow red margins are left. Children thus affected are restless and feverish, there is slight salivation, and sucking or mastication is painful. The ulcers commonly heal in a few days, but may recur frequently in some patients. In adults the aphthæ are rarely so numerous as in children.

Treatment. Antiseptic washes and glycerinum boracis may be used. The application of nitrate of silver in adults at once relieves pain and often quickly cures.

GANGRENOUS STOMATITIS

This disease, also called *cancrum oris* and *noma*, occurs in debilitated children, or those subject to bad hygienic conditions, or those who are recovering from infectious disease, of which measles and enteric fever are most common. It is due to bacterial infection. The changes are very rapid; a small spot of induration appears on the inner side of the cheek, and soon the whole thickness of the cheek is hardened, black in the centre, and reddened around, or, in other words, a slough has formed. If it goes on, the cheek will be perforated, or if it is on the lips, the gum will be invaded, and the teeth will fall out. There is very little pain or fever, but the child rapidly becomes exhausted and dies.

Treatment. The only means of saving the child is the prompt destruction of the part by nitric acid, or its removal by the knife. In addition, the child must be supported by food and stimulants.

THRUSH

Thrush is seen in weak and badly nourished infants, especially in those who are being fed by hand, or are suffering from diarrhœa, and also in adults in the last stages of exhausting diseases, such as phthisis, carcinoma, and enteric fever. Upon the mucous membrane of the lips, cheeks, gums, palate, and tongue, milk-white patches occur, which are irregular in shape, scattered or confluent, slightly raised above the surface, and surrounded by a thin red line. If the patch is stripped off, the mucous membrane beneath is bright red, or even bleeds slightly, and the patch may form again in a short time. It consists of epithelial scales, fat globules, and the spores and mycelium of a fungus, *Oidium albicans*. According to Castellani thrush in the tropics may be due to many different varieties of fungi. The fungus develops first in the middle layers of the epithelium, and spreads thence in both directions to the more superficial and the deeper layers. It is probable that the growth of the fungus is the cause of the stomatitis which accompanies it; but it is stated by Vogel that the deposit is favoured by the secretions of the mouth, which are acid before any white patches appear. Children who have thrush and diarrhœa frequently have excoriations about the anus, which lead to the popular notion that the thrush has "gone through" the child; but though in severe cases thrush may extend to the pharynx and œsophagus, it does not occur on parts covered with cylindrical epithelium. The anal rash is either erythema intertrigo or a congenital syphilide. A certain amount of local discomfort, with pain on swallowing or sucking, results from thrush, but symptoms beyond these are chiefly due to the condition of health preceding it.

Treatment. The general condition of the patient must be improved. In infants the food must be rendered suitable, and the diarrhœa checked. After every meal the mouth should be carefully wiped out with a fresh piece of soft linen, and the patches should be touched with a solution of borax (10 grains to 3j), or a little glycerine of borax should be left in the mouth.

OBSTRUCTION OF THE ŒSOPHAGUS

This is the most important pathological condition of this part of the alimentary tube. The causes are—impaction of foreign bodies, such as false teeth; compression from outside by mediastinal growths and very occasionally by thoracic aneurysms; the growth of carcinomatous or other tumours in the walls of the tube itself; constriction by the contraction of ulcers following injury by corrosive poisons; functional spasm of the muscular walls; and achalasia of the cardia or cardio-spasm; diverticula. The last four conditions will be separately considered.

CARCINOMA OF THE ŒSOPHAGUS

This generally occurs in advanced life, and in males more often than in females. The growth occupies the middle and lower thirds of the œsophagus more often than the upper third; but it is especially frequent opposite the bifurcation of the trachea, and at the cardiac extremity of the œsophagus. It is always primary. In course of time it forms an irregular ulcerated surface on the inside. The tumour partially or completely encircles the tube, extending vertically from 1 to 4 inches; moreover, it often involves the trachea or the root of the lung, or compresses the recurrent laryngeal nerves. The mediastinal lymph glands are enlarged, and not infrequently quite early the cervical glands.

Symptoms. The first and prominent symptom is dysphagia. The patient finds he has difficulty in swallowing solids when he may get fluids down with comfort. The difficulty increases gradually, and at length solid food has to be given up; liquids alone can be taken, and if more than a mouthful is attempted at a time, it is regurgitated, and the patient may choke. Pain is usually absent. After a few weeks the patient begins to waste, and loses strength and energy. The symptoms are generally progressive, but occasionally temporary improvement takes place from crumbling away of portions of growth from the surface, so as to enlarge again the calibre of the œsophagus. If no relief be afforded, death takes place from simple exhaustion, or from complications. Thus in some cases a communication with the trachea is produced by the spread of the growth; food particles are inhaled, and a septic broncho-pneumonia is set up. In others the lung is directly invaded by the new growth, and gangrene or broncho-pneumonia, with which pleurisy or empyema may be associated, carries off the patient. In others, again, compression of the recurrent laryngeal nerves when the growth is at the upper end leads to paralysis of the abductors of the glottis, which may produce asphyxia. Rarely a growth has eaten into the aorta and caused fatal hæmorrhage. Lastly, there may be deposits in other organs, especially in the liver and lungs. Occasionally these are the cause of death, when the growth in the œsophagus has been too slight to produce any difficulty in swallowing.

Diagnosis. Gradually increasing dysphagia in a person over fifty years of age is, in the great majority of cases, due to carcinoma of the œsophagus. Sometimes the fact of dysphagia may be overlooked: food may be retained sufficiently long in the œsophagus above the stricture for its regurgitation to be mistaken for vomiting, both by the patient and by a careless inquirer; and so a gastric lesion may be diagnosed. The patient can often tell the exact level at which obstruction occurs.

The presence of an obstruction can be most readily confirmed by the use of X-rays after a bismuth meal, when the exact position and extent of the obstruction may be demonstrated. The rays will also show whether the lesion is within the œsophagus or is due to pressure from without (*see* Plate 17). When the obstruction is situated in the œsophagus it is still necessary to distinguish between carcinoma, cicatricial or spasmodic stricture, diverticula, and achalasia of the cardia. Direct inspection by the *œsophagoscope* may be employed. In achalasia the œsophagus is greatly dilated, but there is usually not much

dilatation with growth, because in the latter case the obstruction comes on more acutely. A closed hollow tube containing mercury, to make it heavy, may be passed down the œsophagus (Hurst). It will not pass in the case of growth, but will usually pass in the case of achalasia. The presence of enlarged and hard cervical glands is also in favour of growth.

Prognosis. This is uniformly bad. Even if the obstruction is overcome, the malignant growth must be fatal by its further extension within a short time. The duration is generally from six to twelve months.

Treatment. If a bougie, even of small size, can be passed, the passage may be kept open for a time by its use every two or three days. But the maintenance of a channel for the food is best secured by some modification of the method of intubation introduced by Krishaber. A tube is passed through the stricture and retained *in situ* for several days or permanently, and the patient is supplied by that means with fluid nourishment. If these measures are inapplicable, the stomach may be opened by the operation of *gastrostomy*. A diminution of the constriction is sometimes obtained by the use of radium applied locally to the growth of the œsophagus. The application of deep X-rays has given good results.

CICATRICAL STRICTURE

In this, again, dysphagia is the main symptom ; but it differs from carcinoma in this, that it may not advance beyond a certain point, and that it does not lead to any secondary effects, except dilatation of the tube above it. In consequence of this dilatation food often accumulates above the stricture, and is regurgitated after a time.

The **Diagnosis** is determined by œsophagoscopy.

Treatment offers a fair chance of success if the sound or mercury tube can be passed through the stricture into the stomach. It should be used regularly once or twice daily, and attempts should be made to pass larger and larger instruments. Liquid food may be required always. In unfavourable cases *gastrostomy* may be advisable.

SPASMODIC STRICTURE

This is really quite a common condition, although it is not generally realised. There is difficulty in swallowing, accompanied by a painful sense of constriction in the throat and chest (heart-burn). The spasm can be recognised by X-rays (see Plate 18, B). It may be a feature of the dyspeptic symptom complex (see p. 333), and so may be associated with aerophagy. The pain is probably due to the associated œsophageal distension. As the radiogram shows, the spasm is not absolute ; some of the opaque meal manages to get through.

Plummer-Vinson Syndrome. This is a dysphagia occurring in patients with secondary anæmia and sometimes spleno-megaly ; the nails are often spoon shaped. It occurs almost exclusively in women, and most patients have had total extraction of the teeth. The tongue is bald and red and the pharyngeal wall is glazed. The condition was originally recognised by Paterson and Brown Kelly in 1919 (5). The obstruction occurs at the junction of pharynx and œsophagus, and may be due to weakness of the pharyngeal muscles concerned in swallowing or to inability of the crico-pharyngeus muscle to relax. Treatment should be directed to the cure of the anæmia and the dysphagia by the passage of bougies (6).

ACHALASIA OF THE CARDIA

(*Cardio-spasm, Œsophagectasia, Idiopathic Dilatation of the Œsophagus*)

The lower 2 or 3 inches of the œsophageal wall, which may often be seen at autopsy in a relaxed condition a little thicker than the wall above, is the cardiac sphincter. In life the cardia is closed by contraction of both its

longitudinal and circular muscle fibres; it relaxes in front of each peristaltic wave and subsequently contracts firmly again, probably becoming invaginated a little way into the stomach during the process (7). Peristalsis travels rather slowly from the upper end of the œsophagus after swallowing, while a fluid meal is projected straight down. Consequently the bulk of the fluid remains some seconds above the sphincter, before the latter relaxes.

Pathology. In achalasia of the cardia (15, 16) (*a priv.* and *χάλασις*, loosening, slackening) or cardio-spasm, the cardia remains closed; but the tightness of the closure varies in different cases and at different times. It may offer no resistance to the passage of a sound, or the resistance may be insuperable (8). It has been found that Auerbach's plexus, which lies between the circular and longitudinal muscles, is inflamed, and in long standing cases has been destroyed (9). In the early stages the muscular coat hypertrophies above the paralysed portion of the œsophagus, so that food is passed through the cardia successfully, and there are no symptoms. Later, dilatation with hypertrophy in varying degrees takes place and there may be some chronic inflammation of the œsophageal mucosa.

Auerbach's plexus is probably a relay station for the vagus nerve, and it is to be noted that stimulating the vagus in the rabbit relaxes the cardia, so that achalasia may be regarded as a vago-paralysis of the lower end of the œsophagus, with the result that the sphincter does not open in front of peristaltic waves. Since the sympathetic nerve fibres that pass to the muscle fibres are probably intact, and probably cause contraction of the sphincter, it is not surprising that a real cardio-spasm is commonly met with.

Achalasia of the cardia may be due to syphilis, and has occurred in mitral stenosis, where presumably the vagus has been pressed on by the dilated left auricle. It has occurred with gastric ulcer and carcinoma. Usually there is no obvious cause.

Symptoms. The patients suffer sometimes for years from a sense of the food sticking in the throat after it has been swallowed, from actual pain in the epigastrium, from regurgitation of the food, or what is described as vomiting. The condition often comes on gradually, and at first may be spasmodic, recurring from time to time. An X-ray examination after a bismuth meal shows that the œsophagus is dilated into a fusiform body wider at the lower part (see Plates 19 and 20). The dilatation may also be seen with the œsophagoscope. In fatal cases the internal circumference at its widest part has reached a measurement of from 10 to 16 cm. (4 to 6 inches).

Treatment. Some cases have been fatal. In others the patients have got over the difficulty by liquid food, or by extremely careful mastication of solid food. It is often found that a column of fluid the length of the œsophagus forces its way through the sphincter by hydrostatic pressure, until the level has fallen by a certain amount, and this fact enables some food to be taken. Cases have been more promptly dealt with by the passage into the stomach before each meal of a rubber tube filled with mercury or by feeding the patient for four days by means of an œsophageal tube introduced into the stomach and left *in situ* all the time. In refractory cases the stomach is opened through the abdomen and the sphincter dilated with the fingers.

DIVERTICULA

These are pouches in the walls of the œsophagus; they have been divided into (1) pressure diverticula and (2) traction diverticula.

1. *Pressure diverticula* arise from the impaction of foreign bodies, or from other local injury. As a consequence, apparently the muscular coat is weakened, and the mucous and submucous coats are bulged out between the muscular fibres, which do not share in the coverings of the diverticulum. When once this has taken place food accumulates in the sac, which gradually enlarges, so that it may

attain a diameter of 3 or 4 inches. 2. *Traction diverticula*, which usually produce no symptoms, are caused by adhesion of the œsophagus to surrounding parts, *e.g.* through the suppurating or tuberculous bronchial glands, whereby the coats are pulled out in a funnel-shaped manner. Diverticula are usually hemispherical in shape; they are most common posteriorly, at the junction between pharynx and œsophagus, and may project on both sides of the neck, sometimes on the left side only. The next commonest place is near the lower end of the œsophagus (1) (Plate 23, A.)

The **Symptoms** are dysphagia, regurgitation of food, often accompanied by choking or coughing, and foul breath from the decomposition of food in the sac. So much food may accumulate as completely to obstruct the œsophagus. Diverticula are diagnosed by means of X-rays after swallowing some barium (see Plates 18, A and 23, A), and by the œsophagoscope.

Treatment.—The pouch may be removed by operation. In slight cases it is possible to wash it out regularly by mouthfuls of water with subsequent regurgitation.

EXAMINATION OF THE STOMACH

The position of the stomach varies with the position of the patient. In the erect position the cardiac end lies within the bony thorax, while the body and pylorus lie within the abdomen. In the horizontal position the stomach sinks further back beneath the ribs, and only the pyloric part of the stomach lies in the epigastrium. The stomach always contains some air, and this can be recognised by the full tympanitic note which is yielded on percussion of the lower part of the left thorax in front. This area is limited above by the præcordial dulness, and posteriorly by the splenic dulness and pulmonary resonance. It is impossible to separate the note obtained by percussion of the stomach from the note due to air in the intestines, so that this method is of no value in outlining the stomach. The stomach is remarkable for the great alterations in size and position it may undergo, so as to accommodate variable quantities of food. Like other organs it possesses a system of longitudinal and circular muscle fibres, but it has, in addition, an inner system of oblique fibres which pass down from the circular fibres of the œsophagus along the lesser curvature, spreading out like a fan on the anterior and posterior surfaces. It seems likely that this system is concerned with the downward movement of the greater curvature, which takes place as the stomach fills up.

EXAMINATION OF STOMACH BY X-RAYS

This gives valuable information about the shape, size, and motility of the stomach. The patient swallows a meal of porridge or bread and milk containing 2 ounces of a solid salt of bismuth, preferably the oxychloride, or 4 ounces of barium sulphate. The rays are then used, and the position and size of the stomach are indicated by the shadow cast on the screen by the contained metallic salt. The X-rays show that the stomach consists of a vertical part and a horizontal part, separated by the *incisura angularis* on the lesser curvature. The vertical part is divided into two by an imaginary horizontal line at the level of the cardiac orifice. The part above, which usually contains air, is called the *fundus*, the part below the *body*. The horizontal part consists of the *pyloric vestibule* and the *pyloric canal*. The first part of the duodenum during the action of the stomach receives and retains for a time the chyme, so that under the X-rays it shows a dark shadow like the stomach, which often has a triangular shape with its base towards the pylorus, the *duodenal cap*. It is separated from the stomach by the transparent line of the pylorus, in the middle of which the pyloric canal may be seen from time to time, wider or narrower according to the amount of chyme going through. Peristaltic waves of muscular contraction from

the body to the pylorus are recognised by the X-rays with accompanying changes in the shapes of the body and pyloric vestibule. The average position of the normal stomach in the vertical position is such that the greater curvature lies just below the iliac crests (or umbilicus), while the lesser curvature is above it. However, there are wide variations in the position of the stomach quite compatible with health. It may be elongated, reaching low down, and this is sometimes known as the *dropped* stomach which is usually also *hypotonic* (see Plate 21 and also Fig. 48 on p. 340), or may be entirely above the iliac crests, the *hypertonic* stomach (see Plate 22). In the horizontal position, with the patient lying on his back, the stomach falls back beneath the diaphragm, and so lies higher than in the vertical position; it is often divided into two by the vertebral column. It has been observed that a stomach may drop several inches, when viewed in the vertical position, as the result of emotion, or just before a fainting attack, or after a nauseating smell, such as asafoetida. Conversely the stomach tends to be hypertonic when the appetite of the subject is aroused (11). The mean position of the stomach depends on the physical build of the individual. It is high when the body is broad and short, *i.e.* when the circumference of the chest is 3 cms. greater than the body length (see p. 472) and, conversely, low when the circumference of the chest is 7 cms. less than the stem length. The high stomach is usually associated with a high acidity of the gastric juice (12). Members of a family tend to resemble one another in the emptying time of the stomach and in the type of their test-meal curve.

No X-ray examination of the stomach is complete without determining the rate of emptying. The patient is examined two hours, four hours, and eight hours after taking the meal to see if there is any shadow still remaining in the stomach. Normally the stomach is empty in four hours. The small hypertonic stomach is often empty in two hours. Pyloric stenosis is suggested if most of the contents are still present after eight hours. It will be noticed that these times are rather greater than are obtained with the fractional test-meal method.

EXAMINATION OF THE CONTENTS OF THE STOMACH

By the examination of the vomit, and of liquids artificially withdrawn from the stomach during the process of digestion, we may try to ascertain the share which a deficiency of the acids, of the pepsin, or of the motor powers of the stomach may have in different forms of disease, especially in the chronic disorders of digestion.

Vomit. If the patient vomits, the quantity, odour, colour, and consistence of the liquid should be noted. The smell may be modified by substances recently taken, such as volatile oils or alcohol. The liquid may be colourless, or different shades of brown, or stained yellow or green by bile pigment, or pink or red by blood. Often blood is altered by contact with the gastric juice, and a dark brown, opaque fluid is the result, resembling *coffee grounds*. In consistence vomit may be watery, or more or less viscid from mucus, or frothy. The presence of half-digested or undigested food should be noted.

Microscopically animal and vegetable tissues may be detected, such as muscle fibres, cellulose, starch granules, oil drops, red blood corpuscles, leucocytes, and numerous micro-organisms, especially *torulæ*, *sarcinæ*, and sometimes Oppler-Boas bacilli. For chemical examination the vomited fluid must be strained through fine muslin, and the filtrate may be submitted to the tests presently to be mentioned.

Test Meal. The functions of the stomach can be more accurately determined by the use of a test-meal than by examining vomit. Two methods are used: (1) *Ewald's Test Breakfast*. The stomach is first washed out, or the meal, consisting of 2 or 2½ ounces of bread or toast and 20 ounces of weak tea, is given in

CHRONIC DYSPEPSIA

Sufficient has already been said to indicate that chronic dyspepsia is not a disease, but rather a series of symptoms resulting from disturbance of function in the upper alimentary tract.

Pathology. In considering the problem two questions must be kept distinct : (1) What is the organ the functions of which are disturbed in dyspepsia and how does the disturbance produce symptoms ? (2) What is the lesion that causes the disturbance ?

(1) It is at the present time a relatively easy matter to determine in what organ the symptoms are being produced. Pain is the symptom which has been most fully investigated (7). When it is felt high up in the epigastrium by the xiphisternum, or behind the sternum, it is caused by the œsophagus (*see* Plate 18, B, p. 325). Substernal œsophageal pain may be distinguished from cardiac pain by getting the patient to make a swallowing movement. The resulting peristaltic wave that travels down the œsophagus at about the rate of 1 inch a second momentarily relieves the pain, but may intensify it if the pain is very slight. Swallowing does not make a difference to cardiac pain ; but it must be remembered that the two kinds of pain are quite commonly associated. Pain in the stomach is felt in the epigastrium, probably rather lower than the œsophageal pain, and sometimes along the left costal margin, and very commonly round the umbilicus. Pain in the duodenum is felt at about the same level but rather to the right of the middle line. Pain in the jejunum is probably felt below the umbilicus.

Visceral pain may be produced experimentally by blowing up an airbag placed inside a viscus and it is due to the stretching of the pain nerve endings in the wall (21, 22). The presence of such a foreign body in the œsophagus, the organ which has been investigated most completely, causes a series of peristaltic waves to pass down it. Each time the wave passes over the bag and compresses it the pain diminishes or disappears, because the muscle by contracting and lessening its diameter takes the strain from off the nervous structures, even though a high "systolic" pressure is produced by the contraction. The pain reappears as soon as the wave has passed and the wall becomes stretched again during "diastole." In this case the pain is discontinuous or "gripping." The tone of plain muscle has been defined as "tension during diastole," and pain produced experimentally is associated with increased tone. If an incompressible water bag is used the pain becomes continuous and exceedingly severe because the peristaltic wave is held up in its course. The pain is partly due to the continuous stretch, but it is also due to a strain in the nervous structures at the zone between the muscle contracted in systole above the bag and the muscle contracted isometrically and so still stretched by the bag itself just below. Thus the pain is made worse with each peristalsis. This experiment represents the painful spasm associated with the presence of gallstones or renal calculus in the duct. Hollow viscera have a great power of enlarging, *i.e.* altering their "posture," using Sherrington's term, and a foreign body that causes symptoms in the first place ceases to do so when the organ has become big enough by the lengthening or rearrangement of its fibres, so that it can hold it without being stretched. But this process can only take place rather gradually. Hence the postural lengthening of a fibre must be distinguished from its stretching, which causes pain. Counter irritation acts chiefly by causing reflexly increase in posture.

The sensation of sinking or emptiness is produced in the stomach ; the sensation of globus or of a ball of wind in the chest is produced in the œsophagus ; while the sensation of nausea, which is felt at the back and lower part of the throat, is due to reflex disturbances in the upper part of the œsophagus. It is suggested that these sensations are due to specific end organs which react to a lower degree of tension than the pain nerve endings, but as the tension increases these sensa-

tions become replaced, as elsewhere in the body, by the over-riding sensation of pain. The sensation of fulness may be due to extension of the abdominal wall.

Observations carried out by means of a small water bag on patients, while they were experiencing pain, showed the presence of a series of contractions. These have been observed in the œsophagus, stomach, duodenum, or jejunum. Further, the diastolic pressure inside the viscus was increased, though the extent of the increase varied in different cases. The contractions tended to diminish the pain, which was in one case experienced during the subsequent muscular relaxation, during which stretching of the pain endings occurred from the increased diastolic pressure in the viscus. Thus, there was very great similarity between the artificially produced pain and that which occurred naturally. Further, a very close connection was observed between the different viscera. Distending the stomach with air produced peristaltic waves down the œsophagus (the gastro-œsophageal anti-regurgitation reflex). Contractions in the stomach in a patient with hunger pains were followed about one second later by similar waves in the duodenum.

Dyspeptic pain is due to stretching of the pain nerve endings in the wall, and this agrees with other observations that dyspepsia is often the result of unsuccessful attempts at emptying the stomach (24). It is quite possible that in some conditions the muscle may be unduly extensible from fatigue, so that stretching of the pain endings occurs under a relatively low diastolic pressure; but where the pressure is high there must be simultaneous closure of the sphincters, or otherwise the contents would be driven out, and it is quite likely that the dyspeptic syndrome depends primarily on one of these two factors: undue extensibility of the muscular wall; or closure, possibly achalasia, of the sphincters. Localised contractions (spasms) may occur at other places than at the sphincters—in the œsophagus, or duodenum, or on the greater curvature of the stomach. Pain in the stomach is usually of two kinds. It may come on shortly after a meal, or after some hours, when the viscus is empty of food, the so-called *Hunger Pain*. The view is held out that there are two important factors associated with these types of pain, both of which would tend to cause stretching of the wall. These are (1) aerophagy, which may be quite involuntary, and (2) prolonged secretion from the gastric mucous membrane. In fact, these factors have been regarded as compensatory, the aerophagy leading to a rise of pressure and so to the emptying of the organ, and the prolonged secretion acting as a diluent of any noxious substance, in the same way that irritation in the mouth leads to a copious salivary secretion (24).

So far, no account has been taken of hydrochloric acid as a possible pain producer in dyspepsia. Gastric ulcer responded to the administration by stomach tube of 200 c.c. of 0.5 per cent. HCl, in 35 cases with pain, in 24 cases without pain; the figures for duodenal ulcer were 41 and 64. Further, pain was produced in cases where the lesion was distant from the stomach (17), but gastritis cannot be excluded in these cases. Possibly the acid causes pain by increasing the tone of the stomach.

The nausea, sense of fulness or pain of dyspepsia, may lead reflexly to vomiting, or retching, which is the quickest and safest way for the upper part of the alimentary tract to rid itself of its contents. It is due to strong contractions of various skeletal muscles, by which the contents of the stomach are forced out along the œsophagus and through the mouth. In adults vomiting is usually an extremely painful process; but the pain is possibly due to the stomach contents being pressed out through a closed cardia. Vomiting itself is painless, as the writer himself observed when once attempting to push a bag tied on to the end of a stiff catheter down his own œsophagus. It was simply pushed out again by abdominal contractions. The vomiting of babies and hysterical vomiting are painless, and the same is often the case when vomiting is due to intracranial disease. Stimulation of the lower part of the lesser curvature leads to vomiting

movements. The abdominal muscles contract, while the stomach is motionless (11).

(2) *Lesions responsible for Chronic Dyspepsia ;*

(a) The stomach itself may be the primary cause, owing to deficiency in the tone of the muscle, which is often accompanied by dropping of the organ (see p. 339), or to gross organic disease, such as gastric ulcer and carcinoma, and pyloric stenosis, or to chronic gastritis.

(b) Dyspepsia may be caused reflexly by organic lesions situated at a distance, by duodenal ulcer, chronic appendicitis, gall stones, and other lesions of the gall bladder, chronic pancreatitis, lesions of the kidney, particularly movable kidney and calculus. It may be secondary to constipation. In the gastric crises of tabes the primary lesion is in the posterior nerve roots. Angina pectoris may cause a secondary indigestion—*heartburn* in particular. That the origin of the dyspepsia in these cases is reflex, is shown by the following observations. Manipulation over the appendix area in chronic appendicitis has produced a localised spasm of the greater curvature of the stomach. The latter has also been produced by stimulating electrically the peritoneal surface of a duodenal ulcer at operation (11). In a case of jaundice from gallstones, the epigastric pain was found to be associated with the gastric movements. Reflex subternal pain has been noted when manipulating a chronically inflamed appendix (25).

(c) Dyspepsia may be due to more general agencies : pregnancy, sensitiveness to foreign proteins (see p. 138), mental anxiety, overwork, and other debilitating influences, such as prolonged illness, fever, anæmia, Bright's disease, which may act by causing hypotonus of the stomach wall or by interfering with the secretion. Hypoglycæmia may cause a feeling of hunger with pain. The fact that some people may suffer from indigestion all their lives without any obvious cause has led to the suggestion in times past that there is a dyspepsia "*sine materia*." It is, however, probable that careful examination in such cases will always disclose, apart from well-marked organic disease, some lesion, whether this takes the form of weakness of the stomach wall which has been called atonic dyspepsia, or hæmorrhagic erosions in the mucous membrane (24). The present writer has been much impressed with the frequency of slight hæmorrhage in chronic dyspepsia. The majority of his dyspeptic patients show no obvious abnormality in the X-ray appearances of the stomach and duodenum ; but the stools contain occult blood and give a hæmatoporphyrin spectrum ; this is now looked on as due to chronic gastritis. The term *acid dyspepsia* only refers to one symptom of variable occurrence, viz. acid regurgitations, which may or may not be accompanied by hyperchlorhydria. The term *nervous dyspepsia* may be used to describe the dyspepsia of organic nervous disease or disturbed mental states, such as the uneasiness and sinking felt in the epigastrium associated with anorexia and nausea, which are characteristic of certain psycho-neurotic conditions.

Anorexia nervosa. In this disease of mental origin, described by Gull, the patient, usually a young woman, refuses food or takes very little and becomes emaciated. She states she is not ill and may even show exceptional energy. The condition begins in many instances with an attempt to maintain an elegant figure ; the patient overdoes the reduction of weight, and the family become anxious and even nag, which only makes the patient more determined. The under-nutrition may lead to tuberculosis. The treatment must be firm, with rest in bed, a prescribed diet and a special nurse to ensure that the diet is taken. In refractory cases nasal feeding may be required.

Dyspeptic symptoms may persist for some time after the cause has been removed. This is illustrated by an experiment, in which the œsophagus was distended by a bag so as to produce pain. The skin over the sternum was tender and there was pain in the back ; both these symptoms continued for some hours after the experiment was ended, and a severe attack of ordinary dyspepsia

occurred the next day. The œsophageal muscle fibres were probably slightly injured and produced reflex gastric disturbances.

Symptoms. These vary much in different cases.

Pain. Dyspepsia is shown frequently by pain in the epigastric region, which comes on after taking food, and lasts a certain time, gradually subsiding. It is commonly situated around, and particularly just above, the umbilicus or at the level of the xiphisternum or along the left costal margin. It may be felt behind the sternum; this pain is called *cardialgia* or *heartburn*. Often it is felt between the shoulders, going "through to the back." Gastric pains may be referred to the head, producing a brow ache. In other cases pain begins when the stomach is empty, and is relieved by ingestion of food. Instead of pain there may be only a sense of discomfort, tightness, or fulness, or a sinking feeling. Severe pain may be accompanied or followed by superficial tenderness of the overlying skin, or deep tenderness on pressing the abdomen.

Flatulence. This is a common occurrence in all types of indigestion. There is distension of the stomach with corresponding discomfort in the upper abdomen and pain relieved by eructation. Flatulence is usually regarded as due entirely to aerophagy (see p. 338), but it is sometimes partly due to CO_2 , which is probably given off when the alkaline duodenal contents regurgitate and meet the acid gastric contents in the stomach. Thus the gas in the stomach has sometimes been found to contain 10 per cent. CO_2 .

Nausea is a common symptom of dyspepsia, and *vomiting* less frequent, except in alcoholic dyspepsia. The vomited matter is either the ingested food or merely mucus. With repeated emesis bile may be rejected, and a few streaks of blood. *Pyrosis*, or *water brash*, is a name given to a condition in which a quantity of liquid is brought up into the mouth. The liquid is sometimes neutral or alkaline in reaction, and is then commonly believed to consist chiefly of saliva; but it is often acid. There is an accompanying burning sensation felt in the throat and behind the sternum. This is not due to burning by the acid, because acid of this strength does not cause any sensation in the œsophagus.

General Symptoms. The tongue is variable; it is sometimes furred. The fur may be thin and white, or thick and yellow or brown. The furring so often met with may be due to a slop diet, with absence of mastication, or to a deficient flow of saliva, so that the surface scales are not rubbed off. It is accompanied by offensive breath. Constipation is frequent, but may be interrupted by occasional diarrhoea. The appetite is variable; there may be thirst, especially with vomiting. The skin eruptions, erythema, rosacea, urticaria, and acne vulgaris, are often associated with indigestion. The effect upon the body generally, or more correctly upon the nervous system, is seen in malaise, indisposition for exertion, giddiness, subjective sensations of sight, drowsiness, irritability, and mental depression; while slight anæmia or sallowness, some loss of nutrition, and in chronic cases a settled expression of discomfort or anxiety upon the face, are not uncommon. But in other instances there is no general indication whatever of the gastric fault.

Diagnosis. The symptoms of indigestion, and their association with food or hunger, are so characteristic that there is no difficulty in diagnosis. However, diagnosis of the cause of the condition is quite another matter, and in long-standing cases, in addition to a thorough general clinical examination, X-ray examination of the alimentary tract, examination of the stools for occult blood, a test-meal and analysis of the duodenal contents, may all yield valuable information. Even when gross disease of the stomach has been excluded, the presence of occult blood may indicate a hæmorrhagic lesion in the mucous membrane, which may be due to chronic gastritis.

Treatment. It is necessary to treat any disease or faulty habits of life which may be responsible for the dyspepsia. In particular oral sepsis must be attended to. The actual treatment of the dyspepsia may be classified as follows:

(1) *Diet.* All foods containing indigestible residues in the form of pips and skins should be avoided, and solid food must be thoroughly masticated, or minced in the absence of teeth, before it is swallowed. Highly flavoured or spiced sauces, fried food, made-up dishes, condiments, acid fruits, and uncooked substances such as radishes, salad, etc., are not allowed. Food must be simple; but it is impossible to give a hard and fast list of what is allowable. So much depends on the patient's own experience. The following principles should be borne in mind: Flesh foods stimulate the stomach to produce a highly acid juice with much pepsin, and are best digested in such a medium. Starchy foods are digested by the enzyme of the saliva, which requires a slightly alkaline medium, while fats diminish the secretion of HCl and delay the emptying of the stomach. Under ordinary circumstances, and especially if the gastric juice is rather deficient, meat should be given at the beginning of a meal so as to stimulate its production, and the meal may be continued with starchy foods and fats in the form of vegetables, cereals, or fruit, with butter or cream. On the other hand, if the secretion of gastric juice is very abundant, the best results may be obtained by giving fats to begin with, in the form of olive oil, $\frac{1}{2}$ ounce, or sardines in oil, with butter, to be followed by meat and cereals, etc., later. It is probably better practice to lessen the secretion by means of fat than to neutralise the HCl in the stomach after it is formed by drugs. Fat should not be given with flesh foods, and the presence of much fat in pork may be the reason that this is usually tolerated badly. Fish, of which many kinds contain no fat, is usually tolerated best of all.

In more severe cases meals of ordinary size cannot be taken at all, and it is certainly the case that the stomach works best when it contains only a small quantity of food, while pain or discomfort are noticed both when the stomach is full up and when it is quite empty. Hence it is advisable to give food in small quantities at a time and at frequent intervals. Besides a light breakfast, lunch and dinner, something should be taken on waking in the morning, in the middle of the morning, at 4 p.m., and before going to bed at night.

The liquid part of the diet may be regarded from two points of view. There is the volume of fluid that, mixed with the solid part of the meal, produces the optimum concentration for digestion. This should be taken during, or immediately after the meal, and may amount to a pint in the twenty-four hours. There is the additional fluid, amounting to 1 or 2 pints, that is required in the general metabolism of the body. This should be taken a quarter or half an hour before meals. Solids and liquids should always be taken warm. The most suitable fluids are water, *weak* tea or cocoa, and, of course, milk, which is also an important food. Alcohol must not be taken.

Some dyspeptic patients are greatly wasted because they refuse to take food owing to the fear of unpleasant consequences. For such patients rest in bed is essential, and they should be compelled to take food in excess of their basal requirement (see Plate 37) until they regain their weight. It is a good plan to allow a varied breakfast, lunch and dinner, the amount of food being equivalent to the basal requirement, and to prescribe, in addition, 3 pints of milk to be taken on waking, 11 a.m., 4 p.m., and last thing at night.

Drugs. These should only be prescribed when symptoms are complained of in spite of careful regulation of the diet. One of the most valuable is CO_2 , which may be liberated in the stomach and acts by inhibiting gastric contractions, or by causing eructations which relieve the intra-gastric pressure. Two mixtures are made: (1) R Sod. Bicarb. gr. xxx.; Infus. Gent. Co. ad \mathfrak{z} i. (2) R Citric acid, gr. xxx.; aq. chloroformi, ad \mathfrak{z} i. To get a maximal effect with eructations the first mixture is followed immediately by the second. A milder effect is obtained by taking repeatedly a teaspoonful of No. 1, followed by a teaspoonful of No. 2, until the pain or discomfort disappears. Instead of the sod. bicarb., a teaspoonful of equal parts of prepared chalk and mag. carb. may be mixed up in a little water

and used similarly. The mag. carb. will act beneficially in relieving the constipation so often present. The beneficial effect of sodium bicarbonate in relieving pain when given by itself is almost certainly due to this liberation of CO_2 by the acid in the stomach, and not to its alkaline nature. The advantage of giving citric acid is that it makes the action more certain, and it is probably bad practice in most cases to neutralise the HCl of the gastric juice suddenly during digestion. If it is desired to prescribe an alkali independently of the CO_2 effect, magnesium oxide may be used. Where it is suspected that there are lesions in the mucous membrane, bismuth or kaolin may be prescribed with the idea of covering the lesions with a plaster and so protecting them; but they must be given in fairly large doses, *i.e.* 2 to 4 drachms, suspended in water with mucilage. In some cases of indigestion acid hydrochlor. dil. in doses up to a drachm, well diluted with water, taken during and after the meal, is of great benefit, especially when the HCl of the gastric juice is low, and there is much flatulence accompanied by flushing of the face, as in cases of rosacea. Other drugs called carminatives have been taken from time immemorial, and are of subsidiary importance. They are sal volatile, tr. nucis vomicæ, strychnine, ipecacuanha, the vegetable bitters such as calumba root, and the volatile oils, such as oil of peppermint.

Physical Methods. Heat externally applied to the upper part of the abdomen is a powerful help to digestion and probably acts, like counter irritation, by causing reflexly effective visceral movements. Heat may be applied after meals by means of Gamgee tissue, tied round the abdomen, a small portable hot-water bottle, electric or ordinary poultices, or plasters including antiphlogistin or thermogene wool. Other methods applicable to cases of gastroparesis with deficient motor functions on the part of the stomach are described on p. 340. In cases of very severe acute intractable gastric pain, a tube should be passed into the stomach to relieve the pressure. This is preferable to giving morphia, which may, however, be sometimes necessary.

AEROPHAGY

The condition of *aerophagy* or excessive air-swallowing gives rise to one form of flatulent dyspepsia. In the past the accumulation of gas in the stomach was considered to be due to fermentation; but normally this does not occur to any appreciable extent, because the stomach contents are too acid and stay there too short a time. Carcinoma of the stomach, producing pyloric stenosis, is the condition chiefly predisposing to fermentation, because here there are both low acidity and stasis of food. Normally some air is swallowed with food, and is observed in the stomach by X-rays as a clear area just below the left diaphragm giving rise to the tympanitic note obtained on percussing over the upper part of the stomach. It is only when excessive quantities of air are swallowed, and particularly if the process continues between meals, that the condition is known as aerophagy.

Ætiology. There are three groups of cases:—

1. *Dyspeptic.* This is to be regarded (*see* p. 335) as an exaggeration of the normal mechanism by which air enters the stomach (24).

2. *Bad Habits.* This is closely related to the dyspeptic variety and may result from it. The patient feels some discomfort, such as a feeling of tightness or fulness in the epigastrium, which he feels can be relieved by a successful eructation. This feeling may arise spontaneously, or may result from an attack of acute indigestion or an acute gastric ulcer, or some other illness. It persists after the original cause has disappeared. It is not due to excess of gas in the stomach, as the latter is often nearly empty. The patient tries to relieve himself by eructation, but the only effect is to force air into the stomach, so that the discomfort increases; this is repeated once or twice until a considerable amount of air has

walk on hands and feet, which will facilitate the passage of food through the pylorus.

HYSTERICAL VOMITING

Like other hysterical manifestations, hysterical vomiting usually arises from some complaint of which vomiting is one of the symptoms, and is continued owing to "suggestion" after the original complaint has been cured. The vomiting which is a natural accompaniment of pregnancy may be continued in this way in suggestible individuals. Vomiting of this kind may continue after an attack of appendicitis, even when the appendix has been removed surgically. In the war vomiting was one of the symptoms of "gassing," and in many cases hysterical vomiting resulted.

Treatment. As in other hysterical conditions, psychotherapy must be employed. The exact state of affairs must be explained to the patient. All special drugs and diets which were originally prescribed on account of the vomiting, but which may keep up the condition by suggestion, must be removed, and the patient must be encouraged to take ordinary food. In resistant cases the patient may be fed by a thin rubber tube passed through the stomach into the duodenum.

CYCLICAL VOMITING

This is a relatively common complaint among children of three to thirteen years of age both in private and hospital practice, though it is apt to be dismissed under the diagnosis of "bilious attacks" which are attributed to some indiscretion in diet. The attacks occur at varying intervals, and are brought on by mental excitement such as attending parties or doing examinations, by infection such as coryza or tonsillitis, by muscular over-exertion as in competitive games, and by shaking as in a motor drive. There is often a family history; and the subjects of the complaint are sometimes, but by no means always, below par, suffering from constipation listlessness, pallor, "nervousness," nocturnal enuresis, backwardness, ketonuria, etc.

Symptoms. The attack begins suddenly. The symptoms, which last for two or three days, are lassitude, drowsiness, headache, vomiting and prostration. Pyrexia, which may reach 103° F., is invariably present on the first day. There is abdominal pain often in the right iliac fossa and sometimes accompanied by tenderness and rigidity, so that appendicitis is simulated. In a case of the writer's the stools were offensive at the beginning of the attack and unusually copious after it was over. Constipation is the rule during the attack. The vomit as well as the breath of the patient smells of acetone, and the acetone bodies—acetone, aceto-acetic acid, and β -oxybutyric acid—are found in the urine. This ketosis may be present at the beginning of the attack, before the vomiting begins. If the vomiting continues, the child rapidly emaciates, the abdomen is retracted, the face is drawn, and the eyes are sunken. Occasionally the attack is fatal, with headache, delirium, restlessness, convulsions, and collapse or coma from ketosis (see p. 466); and in fatal cases the liver has generally been found to be in a state of fatty degeneration.

Pathology. Hypoglycæmia has been found in some cases; in others the blood sugar is normal. The suggestion has been made that through sympathetic stimulation there is an increased outpouring of adrenalin, which increases glycogenesis (see p. 479) and ultimately leads to the dissipation of the liver glycogen in the form of glucose, which is rapidly burnt up in the body.

Prevention and Treatment. The attacks may be prevented and treated by giving plenty of sugar. If the child is unconscious 5 per cent. dextrose may be administered through a nasal tube passed as far as the pylorus or duodenum (see p. 479), and *per rectum*. The ketosis should be treated by giving plenty of fluids, sodium bicarbonate, etc., but insulin must not be given.

ACUTE DILATATION OF THE STOMACH AND DUODENUM

(Gastric and Duodenal Ileus)

Stomach. Cases of this kind are comparatively rare, though many have now been recorded. Their occurrence is not easily explained; in the majority of cases there is no obvious cause of obstruction, but some have come on after overloading the stomach, especially with vegetables. Excess of gas is rapidly produced, and the stomach becomes distended like the rumen in sheep after eating green wheat. A few cases have occurred after injury, because, presumably, the gastric muscle is paralysed, and more than one-fourth after surgical operations. Here the anæsthetic is supposed to be responsible, especially if it is ether, because patients are apt to swallow air with this anæsthetic.

The onset is generally very sudden; the patient is seized with vomiting, and brings up frequently large quantities of green, brown, or grey fluid. With this are gastric discomfort, pain, and tenderness. The abdomen is generally found to be considerably swollen in its left and lower portions, while the epigastrium is relatively flat. Visible peristalsis is quite exceptional (once in forty-four cases collected by C. Thompson); but varying amounts of resonance, fluctuation, and splashing may be obtained. The patient becomes collapsed, suffers from thirst, the urine is scanty, and the bowels are confined. The symptoms may last a few days.

After death the stomach is found to be enormously distended, stretching down towards the pubes, and there bent on itself with a portion returning up towards the duodenum. The distension sometimes extends some way along the duodenum.

From observations by Box and Wallace it appears that when once the dilatation has begun the distended stomach falling in the abdomen causes a kink in the duodenum, and thereby an obstruction by which the escape of gases from the stomach is prevented, and so the condition is aggravated; and the more the gases accumulate, the more certainly are they prevented from escaping.

Treatment. A tube should be passed so as to remove the contents from the stomach, which are under great pressure. The patient should lie face downwards, and the bottom of the bed should be raised so as to straighten out any kinks.

Duodenum. In this condition there is obstruction due to kinking, possibly by the mesenteric vessels, with or without spasm near the duodeno-jejunal flexure. A chronic condition of dilatation of the duodenum is probably not very uncommon, accompanied by dyspeptic symptoms, distension of the abdomen and bilious vomiting (28).

INFLAMMATION OF THE STOMACH

ACUTE GASTRITIS

Ætiology. Acute inflammation of the stomach, or acute gastric catarrh, may be set up by various forms of irritants. The most intense form of gastritis occurs in poisoning by the strong mineral acids, or other corrosives. The more common cases arise in consequence of the use of indigestible food, such as lobster, crab, or shell-fish, or of unripe fruit, or of flesh, fish, fruit, vegetables, or other food which is in a state of commencing decomposition (*see* p. 367). It is thus common in hot weather. Infants frequently suffer from gastritis associated with enteritis (*see* p. 365). Multiple gastric erosions, described under the heading *acute gastric ulcer*, form one variety of acute gastritis.

Morbid Anatomy. In the well-known case of Alexis St. Martin it was shown that changes quickly followed irritation of the mucous membrane. Red pimples appeared, which were sometimes filled with purulent matter, or there were red patches, or aphthous crusts, or abrasions. The gastric juice was secreted in less

quantity, and mucus was poured out freely. Slight hæmorrhage also occurred sometimes.

Symptoms. In corrosive poisoning the symptoms are acute pain and tenderness in the epigastrium, vomiting of blood and mucus, and collapse; death is a frequent result. These cases are described in works on toxicology.

In the more familiar case of acute gastritis the symptoms are those of acute dyspepsia. The acute gastro-enteritis of infants is described later.

It must be remembered that diseases such as typhoid fever and influenza and appendicitis may begin as an acute gastritis.

Treatment. Food should be stopped altogether for a time. Later a diet should be given as laid down under peptic ulcer. For the pain, hot fomentations or poultices may be used, or, in very severe cases, morphia injected. The same drug will sometimes allay continued vomiting; bismuth and an effervescing draught (*see p. 337*), or 2 or 3 minims of tincture of iodine in a teaspoonful of water given every half-hour, are also useful. Washing out the stomach by siphonage may often be useful at the beginning of an attack.

Acute Suppurative or Phlegmonous Gastritis. Suppuration of the walls of the stomach is a very rare event, and occurs either in the form of a circumscribed abscess or as a purulent infiltration. The symptoms usually resemble those of acute intestinal obstruction, with severe pain in the epigastrium (30).

CHRONIC GASTRITIS

This disease has been a fruitful field of controversy, because of the rapid changes that the stomach undergoes after death from post-mortem digestion. Good fixation, however, can be obtained by injecting 10 per cent. formalin into the abdomen immediately after death. Chronic gastritis arises in two ways: (1) *by the blood stream* from toxic or infective agents which tend to cause involvement of the whole gastric surface; (2) *directly from* the effect on the mucous membrane of injurious agents in the lumen of the stomach; these tend to produce, in the first place, pyloric gastritis (affecting the pyloric part of the stomach), because the contents are more firmly pressed against this part of the stomach than elsewhere (31).

In the earlier stages there may be excessive secretion of hydrochloric acid with a continuing secretion after the meal has left the stomach. Achlorhydria is a final result of chronic gastritis. The term "achylia gastrica" was introduced with the idea that certain people were constitutionally unable to secrete HCl, and it has even been suggested from fractional test-meal figures that 4 per cent. of healthy students may be affected in this way; but it is inconceivable that healthy oxyntic cells could be present in the stomach without a function. Further, even when the free HCl is absent, pepsin and chloride are found to some degree (*see Fig. 47*), and there is probably a little "active HCl." In some cases, at any rate, the achlorhydria is due to excessive duodenal regurgitation (14); or it may require a test-meal consisting of 5 per cent. alcohol or an injection of 0.5 mgm. histamine to elicit the secretion. A persistent achlorhydria or achylia is not a functional condition; in the absence of carcinoma ventriculi it indicates chronic gastritis; it is not uncommon in diabetes and Graves' disease.

Ætiology. There is a familial tendency to chronic gastritis. In children chronic hæmatogenous gastritis may result from acute infectious diseases, and especially acute gastro-enteritis; and in adults it may result from various acute intestinal infections, such as dysentery, the enteric fevers, appendicitis, and also from pulmonary tuberculosis, Graves' disease, pellagra, rheumatoid arthritis and the toxæmias of pregnancy. The pyloric form of gastritis results from poorly prepared food, from drugs, and especially alcohol. These agents act, in the first place, by stimulating the HCl secretions, which may be excessive; it is only later when the gastritis spreads all over the stomach that an achlorhydria

results. Statistically it is found that the frequency of achlorhydria increases with age.

Morbid Anatomy. In the hæmatogenous forms early inflammation shows itself by a round cell infiltration between the gastric glands. Later the glands become atrophied and replaced by granulation tissue, or in some places they are cystic; sometimes intestinal epithelium with goblet cell and even Lieberkühn's glands appears. In follicular gastritis there is a formation of typical lymphoid follicles. Similar changes may occur in the pyloric form, but, in addition, a mammillated condition of the mucous membrane, and even a regular polyposis, may be obvious, and superficial erosions are characteristic.

Symptoms. In the hæmatogenous form the commonest symptoms are flatulence, constipation or diarrhœa, or both alternately, a sore tongue with atrophied papillæ or ulceration as in pernicious anæmia, fatigue, depression, sleeplessness and migraine. There may be no dyspeptic symptoms; the presence of these would appear to depend on the activity of the inflammation. There is occult blood in the stools. Pyloric gastritis, on the other hand, may produce exactly similar symptoms to those of juxta-pyloric ulcer (*q.v.*), with hypersecretion of HCl, hunger pains and even hæmatemesis. Further, it has been found, on examining microscopically the pyloric part of the stomach which has been removed at operation for peptic ulcer, that a pyloric gastritis is frequently present and also a duodenitis, which suggests that peptic ulcer is frequently merely an advanced form of this condition. Chronic gastritis, in the later stages when achlorhydria has developed, is associated with a microcytic anæmia (simple achlorhydric anæmia), pernicious anæmia and subacute degeneration of the spinal cord; it predisposes to carcinoma ventriculi; but there is difficulty here, as achlorhydria is much commoner in women, but carcinoma of the stomach is much commoner in men.

Diagnosis. The significance of achlorhydria has already been dealt with. A dyspepsia associated with hypersecretion may be attributed to gastritis, especially the pyloric form, if other causes have been excluded.

Treatment. For achlorhydria 1 drachm of acid hydrochlor. dil. in 4 ounces of water should be supplied with meals, while other fluids must be taken half an hour before meals. The treatment of dyspepsia has already been considered.

PEPTIC ULCER

(*Ulcer of the Stomach and Duodenum*)

Ulceration is very apt to occur on mucous membranes that habitually come into contact with the acid gastric juice. Such ulcers are conveniently called *peptic*, and there are several varieties. The *acute* ulcer, most commonly multiple, varies in size from a tiny superficial erosion of the mucous membrane up to an inch in diameter. *Chronic* ulcers, usually single, are best classified according to their positions: (1) in the body of the stomach, usually on the lesser curvature, and on the posterior rather than the anterior surface; (2) in the pyloric part of the stomach, also usually on the lesser curvature and posteriorly, but not extending nearer to the pyloric ring than $\frac{1}{4}$ inch; (3) in the first part of the duodenum, usually posteriorly. In this connection it must be remembered that the first part of the duodenum has a completely different function from the other parts, but resembles more closely the pyloric part of the stomach. Thus the acid chyme is pushed through the pylorus into the first part of the duodenum, and remains there until the next peristaltic wave pushes some more chyme forward to take its place. Ulcers situated actually at the pyloric ring are uncommon. Ulcers in the body of the stomach often have distinct characteristics, and much confusion has arisen from grouping the pyloric ulcers and these ulcers together under the heading *gastric*, merely because they both happen to be in the stomach, whereas the pyloric ulcers have a much closer affinity with those in the duodenum.

Pyloric and duodenal ulcers should be considered together as *juxta-pyloric*; ulcers both of the stomach and duodenum may be present simultaneously.

Ætiology. Acute peptic ulcers occur scattered about irregularly, and are probably quite common in both sexes; but they are commoner in women and tend especially to affect the body of the stomach. Some ulcers in this situation become chronic, though most of them heal readily enough. However, they may come again later and again heal. A continuation of this process, viz. acute relapsing ulceration, tends to the formation of an hour-glass stomach, which is much commoner in women than in men (32). While peptic ulceration in women occurs most commonly in the body of the stomach, in men it occurs most commonly in the *juxta-pyloric* region and does not heal so well. Consequently we find (1) that chronic duodenal ulcer is four to six times commoner in men than in women, whereas (2) chronic gastric ulcer is about equally common in both sexes, since the preponderance of the male ulceration in the pyloric region about neutralises the female preponderance in the body of the stomach, and (3) ulcer scars are more commonly met with in the body of the stomach (33). It has recently been claimed that in women duodenal ulcer is commoner than gastric ulcer, but that the symptomatology of cholecystitis is imitated (29). Peptic ulcer has a tendency to run in families. Very occasionally gastric ulcer is due to syphilis. Painless hæmatemesis, so common in young women, which has been called *gastrostaxis*, is due to acute ulceration. The lesions are often so small that they are called hæmorrhagic erosions, and so widespread that the mucous membrane may present the appearance of "weeping blood." Such a condition is an exacerbation of chronic gastritis. The relation of peptic ulcer and pyloric gastritis has been considered. Duodenal ulcer has been described in infants.

Morbid Anatomy. *Acute Ulcer.* In the earliest stage there may be a superficial necrotic lesion with reddened margins situated on a slightly raised and thickened patch of mucosa. Then excavation occurs and tiny vessels are exposed in the floor, which is often covered with a thin black layer of altered blood. This layer separates, leaving a smooth clean floor before healing. The ulcers have a punched-out appearance; the smaller ones are quite shallow, affecting only the mucosa; the larger ones penetrate the muscular coat and have a "terraced" appearance, because the ulcer becomes narrower the more deeply it penetrates. The *chronic ulcer* is generally much larger, and may reach a diameter of 5 or 6 inches. It extends deeply into the wall of the stomach; the edges are thickened and raised, from infiltration with inflammatory fibroid material, and overhang the ulcerated surface; and the thickening extends some little way into the surrounding mucous membrane. When *active*, the chronic ulcer has a narrow zone of sloughing inflammatory exudation in the floor. When *healing*, the floor becomes clean by separation of the slough, the margins become flatter, and epithelium grows inwards over the floor. In a *callous* ulcer the process of healing remains stationary.

When the ulceration reaches the peritoneum this may rupture so that perforation takes place. This is commoner on the anterior than the posterior wall of both stomach and duodenum. The visceral contents escape into the peritoneal cavity and set up intense general peritonitis, or a more localised abscess, *perigastric abscess*, or *subphrenic abscess* (see p. 416). This abscess may perforate the diaphragm and set up pneumonia, pleurisy or pericarditis, or it may perforate the colon or duodenum, or open again into the general peritoneal cavity. The term *chronic perforation* is used for an ulcer which leaks into the peritoneal cavity a little at a time over a long period, so that adhesions form and shut off the main peritoneal cavity. These may be so dense as to suggest carcinoma. The stomach becomes connected through the ulcer with a large cavity outside the stomach, sometimes involving the greater part of the lesser sac. More often the inflammatory process, extending to the serous surface, causes the stomach to

adhere to one of the adjacent parts before perforation can occur. This is most frequently the pancreas or the left lobe of the liver, but adhesion also takes place occasionally to the diaphragm, spleen, colon, anterior abdominal wall and even the suprarenal capsule. The ulcerative process then extends into the newly attached organ, and cavities may be formed in the liver and pancreas. Very rarely fistulæ may be produced into the colon or through the skin. Hæmorrhage is a common accident, mostly from gastric vessels in the wall of the ulcer, but sometimes from the splenic artery after adhesion to, and ulceration of, the pancreas.

But many ulcers recover completely, and small scars are often found. They are often very difficult to see, and are frequently missed at post-mortem. Larger scars, which are thick and puckered, may themselves give rise to considerable trouble. Thus at and near the pylorus they may by their contraction cause *stenosis*, and consequent *dilatation of the stomach*; if near the cardiac extremity, the stomach may be contracted. Sometimes an *hour-glass contraction* is due to ulcer. *Perigastric adhesions* sometimes give rise to pain and dragging sensations. The relation of gastric ulcer to carcinoma is considered on p. 353.

Pathology. Bolton produced ulcers experimentally in animals by preparing a special gastrototoxic serum and injecting it beneath the peritoneal surface of the organ. The cells were devitalised, and the HCl of the stomach took part in the digestion of these cells with the formation of an *acute ulcer*. No ulcer was formed if the stomach contents were kept alkaline. The naturally occurring acute ulcer in man can be explained along these lines. There may be several different factors that play the part of Bolton's gastrototoxic serum, such as embolism, from septic foci elsewhere, a chronically inflamed appendix, or gall-bladder, septic teeth, extensive and infected burns; or venous thrombosis of small vessels or hæmorrhage, sometimes due to portal obstruction. The stomach may on rare occasions be injured directly by a blow, or there may be a primary pyloric gastritis. The HCl and pepsin digest away the necrotic tissue forming the ulcer. Bolton's ulcers, experimentally produced, healed readily in a few weeks. The rate of healing was very little altered by trying to infect the ulcers with bacterial cultures, or by bleeding the animal so as to make it anæmic. Healing was, however, definitely delayed by feeding the animals (cats) with meat instead of milk, and by producing some occlusion of the pylorus, so that there was delayed emptying of the stomach. In monkeys administration of HCl caused some delay in healing, and this was greatly accentuated by partially occluding the pylorus. There is no doubt that in man many ulcers heal readily enough, but there is a proportion of them that persist and gradually change into the chronic ulcer for two possible reasons: (1) The hydrochloric acid may play a part in this change; but observations that gastrojejunostomy, in the case of juxta-pyloric ulcer, produces very little alteration in the HCl of the gastric juice suggest that this factor is not of great importance (39). (2) Increased tension of the stomach wall leading to feelings of pain or discomfort are also common, and these movements, which are probably associated with the closure of sphincters or spasms in various parts of the upper alimentary tract or chronic duodenal ileus (40), may be an even more important factor, since relatively high pressures have been recorded (7). It is possible that a vicious circle becomes established, the ulcer causing the high tension in the first place, which tends to prevent it from healing. The hydrochloric acid may perhaps act by producing reflex closure of the pylorus and so increasing the mechanical factor. Finally, mention must be made of the fact that strains of streptococci of low virulence have been isolated from tonsils and from various sources, which produce peptic ulcer in animals on intravenous injections, and the same micro-organisms have been found naturally occurring in the ulcers of man, so that they appear to have a specific affinity for the stomach and duodenum, in the same way that typhoid bacilli attack the gut. This phenomenon has been

called "elective localisation" (41). Simultaneously with peptic ulcer there may be appendicitis and cholecystitis—the abdominal triad—and the same streptococcus has been isolated from all three lesions (29).

Symptoms. *Acute Ulcer.* In a number of cases the first symptom is due to hæmorrhage from the ulcer. In cases of *gastric ulcer* this often leads to *hæmatemesis*, or vomiting of blood, which may be pure or mixed with gastric contents. The patient feels faint, has a sense of oppression in the epigastrium, and in a few minutes vomits the blood, which may amount to 1 or 2 pints. Some of the blood discharged into the stomach finds its way into the intestine; the hæmoglobin is converted into hæmatin and hæmatoporphyrin, and the motions subsequently passed are black, treacly, or tarry, constituting *melæna*; these may appear some hours after the hæmatemesis has ceased. The vomiting of pure blood is rarely fatal; it usually ceases entirely, and may not be repeated. High degrees of anæmia and weakness result from the loss of blood. In *duodenal ulcer* hæmatemesis may also occur; but the tendency is for most of the blood to be discharged *per rectum* as *melæna*. Apart from hæmorrhage, peptic ulcer may produce dyspeptic symptoms of acute onset, associated perhaps with prolongation of the gastric secretion, as already described (on p. 335). *Perforation* of the ulcer rarely gives the first indication of its presence.

Chronic ulcer of the body of the stomach is characterised by *pain* which is felt deeply in the epigastrium, just below the ensiform cartilage, sometimes nearer the umbilicus, or to the right or left of the middle line, the right more often than the left. It is brought on by the ingestion of food, appearing from half an hour to two hours after a meal; it may continue intense until vomiting takes place, by which it is generally relieved, or it subsides as the food leaves the stomach. In character it is piercing, boring, tearing, or burning, and more severe than in any other gastric disorder. Sometimes there is pain in the back, between the eighth dorsal and the second lumbar vertebræ, and even over the forehead. Associated with the pain, and often noticed for some little time after the pain has disappeared, there is cutaneous hyperæsthesia or soreness experienced when the skin is lightly pinched. Heartburn (*see* p. 336) is rather common, but hunger pains are only found in one quarter of the cases; but complete emptying of the stomach is often delayed, though the food passes out readily to begin with (33). The secretion of HCl is found to be normal (39).

Chronic Juxta-pyloric Ulcer. The pain resembles in its character that already described; but it is sometimes felt to the right of the umbilicus, and it comes on two, three or four hours after food, or wakes up the patient in the early morning. The pain is relieved by taking some food, and so has been called *hunger pain*. There are two types of cases: (1) When the pylorus opens freely, the stomach readily empties itself of food. There is marked hyperchlorhydria of the resting juice, perhaps most marked in duodenal ulcer, and there is a prolonged secretion of highly acid juice after the stomach is empty; (2) When the pylorus opens freely to begin with, but later there is spasm; this constitutes the early stage of a pyloric stenosis. The hydrochloric acid of the gastric juice shows the climbing curve also with prolonged secretion and hyperchlorhydria; but there is delay in emptying and vomiting is common. Hæmorrhage may be severe or fatal when a large artery is eroded. In this case the vomited blood retains its arterial brightness. There may be remission of symptoms, but the history of the disease is not so long as in ulcer of the body of the stomach, because, owing to the beginning pyloric stenosis, the symptoms are usually more severe and radical treatment more necessary.

In chronic peptic ulcer other symptoms described under chronic dyspepsia, such as flatulence and distension, are commonly present, the continued pain, the defective assimilation of food from vomiting, and the loss of blood, naturally impair the general condition of the patient sooner or later and cause anæmia; but there is no fever, the tongue is clean, and the appetite is often very good and

nausea absent. Constipation, however, is frequent. Examination of the abdomen generally reveals nothing ; there may be some hardness or tenseness of the abdominal walls. Only in the case of old ulcers with much thickening, or adhesion to other organs, can anything like a tumour be felt ; and if pyloric stenosis results, the dilated stomach may be recognised (*see* Plate 26), and there may be visible peristalsis.

Diagnosis. In a case of hæmatemesis where hæmorrhage is the only symptom cirrhosis of the liver and splenic anæmia must be thought of before the diagnosis of acute ulcer of infective origin is made. Hæmatemesis must not be confounded with hæmoptysis or with vomiting of blood after epistaxis. The complaints likely to be confounded with chronic peptic ulcer are the various forms of dyspepsia already described, carcinoma and chronic appendicitis (appendix dyspepsia), or the dyspepsia associated with gall stones.

A test meal which shows a high concentration of " free " or " active " HCl will favour juxta-pyloric ulcer. The presence of a trace of blood in the meal is suggestive, but it may be produced by slight trauma of the mucous membrane caused by the tube. The presence of occult blood in the stools and of a hæmatoporphyrin spectrum in the fæcal extract is, however, valuable evidence in favour of gastric or duodenal ulcer.

The most valuable evidence in favour of chronic gastric ulcer is obtained by X-rays after an opaque meal. A small projection in the shape of a funnel or sac (*nitch* or *diverticulum*) is seen on the edge of the stomach near the lesser curvature (*see* Plate 23, B). The projection depends on the presence of the stomach contents in the cavity of the ulcer, and will not be seen if the cavity is closing up in the process of healing. An ulcer cavity on the posterior surface of the stomach will not be seen when the stomach is full. In order to diagnose it, it is necessary, after the patient has taken the first mouthful, to manipulate the abdominal wall so as to spread the opaque material over the stomach wall. Some of it will stick in the ulcer cavity, and show it up. In some, but not in all, cases the projection is associated with a deep indentation of the greater curvature or *notch* or *incisura* at the same level or slightly above or below it, due to spasm, and there may be localised painful spots. The indentation may be seen alone without the projection, and may remain constant in position when from the symptoms it would be judged that the ulcer had healed. In such a case the deformity may become permanent owing to the deposition of fibrous tissue, and a cicatricial *hour-glass stomach* is produced. The indentation may occur with duodenal ulcer or appendicitis, and so by itself it is not diagnostic of gastric ulcer. It is also important to see how long it takes for the stomach to empty, so as to detect pyloric spasm as well as cicatricial pyloric stenosis. A positive Wassermann reaction will suggest that a gastric ulcer is syphilitic, and anti-syphilitic measures should be instituted in addition to other appropriate medical treatment (38).

Chronic duodenal ulcer may be diagnosed by the X-ray appearance of the duodenal cap. The latter is shown up best if sodium bicarbonate is given with the opaque meal. The appearances are very variable, depending partly on the cavity of the ulcer and partly on spasm of the muscular coat (*see* Plates 24, 25).

Diverticula of the duodenum are shown up by X-rays and are comparatively common ; they may be indistinguishable from ulcer and doubtless in some cases are healed ulcers ; but the symptoms are often like those of ulcer. The pocket is usually the size of a finger tip and is situated at the junction of the first and second parts, but may be in the second and third parts and in the small intestine, but here they do not so often give rise to symptoms. Adhesion about the gall bladder and twisting at the junction of the second and third parts give appearances resembling diverticula (34).

Prognosis. Analysis of the cause of death in 150 cases of chronic gastric ulcer and 200 cases of chronic duodenal ulcer considered together showed that in

51 per cent. it was perforation, which was commoner in duodenal than gastric ulcer, 9 per cent. hæmorrhage, 5 per cent. the effects of long obstruction, carcinoma, etc., 17 per cent. the result of operation, particularly pulmonary complications, and in 18 per cent. the cause was not related to the ulcer (37). In *acute* ulcer hæmorrhage, though common, is rarely fatal, and perforation is also rare. In *chronic* ulcer hæmorrhage may be fatal and perforation is not uncommon, but these complications will nearly always be preceded by severe pains of some duration, which indicates that efficient treatment is essential. The absence of pain suggests that the ulcer is healing and these complications are then unlikely. Chronic ulcers of the largest size will heal under conditions favouring the absence of symptoms, especially pain, though the process may take months.

Treatment. The most important indication is to give the stomach as much rest as possible. The patient must go to bed and not smoke, and for some weeks afterwards should take but little exercise. The old method of trying to "rest" the stomach by not allowing the patient to take food by the mouth for weeks at a time, but feeding him rectally instead, has now been given up; the well-known "hunger contractions" of the empty stomach show that this treatment was based on a fallacy. Rest can best be obtained by taking food a little at a time and at frequent intervals.

The patient is fed at hourly or two-hourly intervals during the day, but complete rest is given during the night. Milk will form the chief article of diet, and raw eggs may be mixed with it, if the patient can tolerate them. Junket and cream, arrowroot, custard, potato or artichoke purée, Benger's food, red currant jelly and the juice of fresh fruit can also be given from the beginning of the treatment. Later on, weak tea, thin bread and butter and toast, pounded fish, minced chicken, minced meat can be added. Half an ounce of olive oil may be given before the more substantial meal. Alcohol and smoking are not allowed. At no time should the patient ever feel hungry; *e.g.* on waking in the night an extra feed *may* be required. Treatment in bed should be carried out for fourteen days after pain, rigidity, occult blood in the stools and X-ray evidence of ulcer have disappeared.

Alkalies, and in particular sodium bicarbonate, are much used in treating peptic ulcer, and in Sippy's method the attempt is made by frequent doses to keep the gastric contents always alkaline; in fact, in some cases enough alkali has been given to cause nephritis and uræmia (42). A doubt has already been expressed as to whether the acid of the gastric juice is really responsible for keeping up a chronic ulcer, and in any case it would seem more rational to counteract a hyperchlorhydria by means of giving fat in the form of cream or olive oil, etc. The writer's plan is to use two powders alone—prepared chalk and a mixture of magnesium carbonate and prepared chalk—a teaspoon of either to be taken after each feed in water or milk, with a double dose the last thing at night. The bowels are regulated by increasing the number of administrations of the second powder. These substances act beneficially by relieving pain, including heartburn; but this may be because CO_2 is liberated; and very successful results may be obtained by prescribing a little citric acid at the same time when there is hypochlorhydria (*see* p. 338). The aim should be to keep the patient for a prolonged period free from pain or discomfort, and so the ulcer will slowly heal. Other drugs for treating pain are tinct. belladonnæ \mathfrak{M} v—x. and atropine injections gr. $\frac{1}{100}$, opium in small doses of the extract or tincture, or the liquor morphinæ hydrochloridi in 10 or 15-minim doses. In severe cases the hypodermic injection may be used, but the opiate treatment must always be discontinued as soon as relief is obtained. Local applications to the epigastrium may be used (*see* p. 338). In cases where the pain and discomfort does not rapidly disappear with the medical treatment described above, recourse may be had to feeding through a duodenal tube kept in position for a week at a time, and this is applicable especially to chronic gastric ulcer.

If a profuse hæmorrhage occurs, the patient must be kept at rest under morphia, and calcium chloride gr. i in 100 minims of water may be injected intramuscularly (*see also* p. 175). A stomach tube should be passed and the contents removed with a Senoian's evacuator and the stomach washed out with small amounts either of ice-cold water or water at 130° F., so as to stimulate it to contract down. Adrenaline (20 to 30 drops of a 1 in 1000 solution) may be left in the stomach. No food must be taken for twenty-four hours after the hæmorrhage has stopped, but water may be drunk in amounts not exceeding 5 ounces at a time. Ice should be applied to the epigastrium. When death is threatened, blood transfusion may be carried out. This does not tend to keep up the hæmorrhage, as might be expected owing to the rise of blood pressure. Surgical measures, such as suturing the bleeding vessel, have also been successful in stopping hæmorrhage from a chronic ulcer.

If a patient known to suffer from gastric ulcer is seized with the symptoms of perforation (*see* Peritonitis), the abdomen should be opened as soon as possible—*i.e.* within five or six hours—the peritoneal cavity washed out, and the ulcer sutured.

In ulceration of old standing, with frequent recurrence of pain and vomiting, or of severe hæmorrhages, or with evidence of much thickening about the ulcer, operation will naturally be considered. This has been most successful in cases where the ulcer is accompanied by stenosis of the pylorus or cicatricial hour-glass stomach. The operations practised for chronic gastric ulcer are gastro-jejunostomy, sometimes with excision of the ulcer, or its destruction by the cautery or with jejunostomy, gastro-gastrostomy, partial gastrectomy (removal of pyloric part of stomach), and the median "sleeve" resection of the stomach. For chronic duodenal ulcer the operations are excision of the ulcer, gastro-duodeno-pyloroplasty and gastro-jejunostomy.

Prevention. When an ulcer is healed, care must be taken to prevent a relapse, which readily occurs. Septic foci in the teeth, tonsils, appendix, gall-bladder, etc., must be dealt with, if necessary by operation. Meals must be light and taken at frequent regular intervals, and the rules of diet on pp. 337, 349, should be followed. Alcohol is best avoided, though light wine and very weak whisky may perhaps be allowed at meals. He must eat slowly and masticate thoroughly and only smoke a little. The teeth must be looked after. The patient must be prepared to go to bed on a diet principally of milk at the onset of pain, and olive oil may be taken before meals.

Sequelæ of Gastro-jejunostomy. Statistics show that a cure is by no means invariable after gastro-jejunostomy. Out of 108 cases operated on at Guy's Hospital between 1910 and 1915, 65 per cent. were cured or much improved seven years later, while 35 per cent. were unsatisfactory. The best results were in pyloric stenosis (43). In a series of fifty-one cases complaining of symptoms subsequent to gastro-jejunostomy, examination showed a variety of conditions: Gastro-jejunal or jejunal ulcer (20), delay in stomach (18), recurrent duodenal ulcer (10), regurgitation of bile (8), dyspepsia due to operation (24), etc. The symptoms complained of were pain (50), flatulence or distension (40), vomiting (40), weakness (38), constipation (38), diarrhœa (22), and headaches (22). Patients may show glycosuria and there may be deficient assimilation of fat (45).

Gastro-jejunal and Jejunal Ulcers. The gastro-jejunal ulcer occurs at the actual site of the anastomosis, and in most cases it is due to the use of unabsorbable suture material or hæmatoma or bruising by clamps at the operation (44). Jejunal ulceration occurs just beyond the junction, and is evidently due to the presence of the same factors as cause a duodenal ulcer, such as infection from focal sepsis that has not been eradicated, hyperchlorhydria which has persisted in spite of operation, and spasms round the stoma or in the descending loop and altered motility. The symptoms are the same as in duodenal ulcer, except that the site of the pain is now rather lower and on the left side of the abdomen.

When the ulcer has burrowed down on to the colon, there may be epigastric pain on defæcation. Sometimes jejuno-colic fistulæ occur, with vomiting of fæculent material. These are usually not seen by X-ray examination after an opaque meal.

Treatment. Secondary ulceration must be treated on the same lines as peptic ulcer. Operation may be required and if the pylorus is acting well, the gastro-jejunostomy may be undone. The treatment of the other conditions depends on the X-ray findings. If the stomach empties too rapidly, liquids should not be taken at meals. Massage and gastric lavage may be beneficial. Usually these patients do not tolerate fat well.¹

DILATATION OF THE STOMACH

Dilatation of the stomach may take place very gradually (chronic dilatation), or may occur quite suddenly (acute dilatation). The latter has been already described.

CHRONIC DILATATION

This results (1) from the various conditions which produce obstruction of the pylorus, so that the stomach wall is also hypertrophied, and (2) from conditions which alter the contractile power of the muscular walls (*see* Gastroparesis). The causes of obstruction are cicatrices of ulcers of the pylorus or duodenum; spasm of the pylorus secondary to neighbouring ulceration; carcinoma of the pyloric part of the stomach; hypertrophic stenosis of the pylorus; pressure from without, binding down by adhesions, or dragging of a prolapsed kidney; and, quite exceptionally, cicatrices from corrosive substances, which, however, generally involve the œsophageal aperture.

Physical Signs of Dilatation following Pyloric Stenosis. In marked cases, when the abdomen is exposed, it is seen to be asymmetrical, presenting a rounded *prominence* in its left half. This prominence extends below the level of the umbilicus, its lower margin having a curve convex downwards and outwards, from the lower part of the costal margin to the right of the middle line. From time to time a wave of peristaltic movement passes from left to right and downwards across the prominent part. A portion at the extreme left, about the size of the palm of the hand, quickly forms a convex prominence, with a decided amount of resistance to pressure; in a few seconds the swelling subsides, and another part, more to the right, swells up for a similar length of time. After each successive portion of the stomach wall has become hard and prominent the whole subsides. This phenomenon occurs spontaneously, or may be set up by manipulating the abdominal wall, or flicking it with the finger sharply, or sometimes on mere exposure of the abdomen. It is called *visible peristalsis*. By sharp movements of the abdomen, as when the patient is shaken, the liquid contents are set in motion, and *splashing* can be heard and felt. This, however, has no significance unless it can be recognised over an abnormal area, as, for instance, as low as an inch from the umbilicus, or at a time when normally the stomach should be empty, namely, six or seven hours after a meal.

A striking feature of many cases of chronic dilatation is the manner in which vomiting takes place. The food is retained for three or four days, and then 2 or 3 pints of fluid are vomited at once. It is generally of a greyish-brown colour, frothing on the surface; and on microscopic examination it shows numerous yeast spores, sarcinæ, and long rod-shaped bacilli, the *Oppler-Boas bacilli*. In other cases the vomiting is more frequent, and the quantity ejected is less at a time.

In addition to the vomiting, the patient suffers from discomfort or actual pain,

¹ The numbers in *italics* refer to percentages.

which is increased as the contents accumulate, and is temporarily relieved after they are evacuated. Great thirst, loss of strength, emaciation, pallor, and constipation are also observed. Much mental depression, and sometimes tetany and convulsions, may also occur. The urine is scanty, and there may be ketosis.

Diagnosis. This depends ultimately on an X-ray examination after an opaque meal (see Plate 26). The stomach is enlarged downwards and to the right. At first there may be over-active peristalsis with rapid emptying. Peristalsis then becomes intermittent and the waves of variable depth, so that there is a residue of about half the meal in six hours. In the later stages peristalsis may only be seen occasionally and it may travel in the reverse direction, and the stomach may remain full after twenty-four hours. A fractional test meal (see Fig. 46, p. 331) also shows delay in emptying and a steadily rising free HCl curve.

Prognosis. Dilatation from narrowing of the pylorus must persist as long as the disease which causes obstruction, and treatment other than surgical can only be palliative.

Treatment. The treatment is surgical and a gastro-jejunostomy is most often performed. As a palliative measure the operation of washing out the stomach with normal saline (*lavage*) is often of great value. The over-distended organ is thus relieved of the accumulation of liquid and undigested food, and any catarrh which may co-exist is at the same time benefited. A rubber tube attached to a funnel is introduced into the stomach; the stomach is filled by raising the funnel above the level of the mouth and pouring in water; it is emptied again by depressing the funnel and inverting it into a suitable vessel, or better by means of a Senoran's evacuator. The object of using saline is to counteract tetany. The washing should be done once daily, half an hour before the largest meal.

HOUR-GLASS CONTRACTION OF THE STOMACH

This condition is practically always due to cicatrization of a chronic gastric ulcer, although occasionally perigastric adhesions may fasten the stomach to the liver, and produce a similar appearance by kinking. Carcinoma may produce narrowing of the stomach, and in gastropexia the stomach is divided into an upper and lower compartment with a narrow neck intervening; but there is no difficulty in differentiating these conditions from true hour-glass contraction.

The symptoms are those of the associated gastric ulcer; but when the latter has completely healed and the constriction is considerable, the patient will complain of being only able to take small quantities of food at a time, larger quantities being immediately regurgitated, so that œsophageal obstruction may be suspected.

Diagnosis. This is carried out by means of X-rays after an opaque meal. The stomach is divided into two compartments connected together by a narrow neck, which joins the upper compartment on the right side and not at its most dependent part. This is quite characteristic, and serves to distinguish the condition from the sagging of the stomach in gastropexia. If the ulcer is not completely healed, there may be some spasm of the musculature in addition to the cicatrization; this makes the obstruction still greater, so that only the narrowest streak of barium joins the two compartments. When spasm is present it may relax somewhat on cautious manipulation or after a dose of belladonna. An active ulcer may or may not be present, and is shown as a projection to the right of the neck (see Plate 27).

In carcinoma the growth will be seen projecting into the stomach, as a clear area (see p. 355); but if it arises from the ulcer, the X-ray appearance may be the same as in hour-glass contraction.

Treatment. The only efficient treatment is surgical; the constriction can

be widened, or the proximal cavity can be united to the distal cavity, or to the jejunum.

CONGENITAL HYPERTROPHIC STENOSIS

This is a form of pyloric obstruction of which the symptoms appear as a rule from a few days to six or seven weeks after birth, most commonly during the first four weeks of life (47). The disease is about five times as common in boys as girls. The symptoms consist of vomiting and constipation owing to the smallness of the amount of food that reaches the intestine, and emaciation; and the vomited matters are often abundant and thrown up with much force. At first they consist of food, but later there is mucus, and altered blood, as gastritis becomes established; but very occasionally bile. The peristaltic movement from left to right, so characteristic of pyloric stenosis, will be seen; and in nearly all cases—a careful and prolonged examination may be necessary during and after a feed—a tumour or thickening, $\frac{1}{2}$ or $\frac{3}{4}$ inch in diameter, will be found to the right of the middle line, a little below the costal margin, varying in hardness from time to time with the contraction of the pylorus, and so distinguishable from scybala. Visible peristalsis may occur apart from organic disease, so that the presence of a tumour is necessary for certain diagnosis. X-rays may also be helpful.

The thickening is a hyperplasia of the muscular fibres of the pylorus, chiefly of the circular coat, and is probably developed during foetal life; within the thickened mass the mucous membrane is thrown into folds.

Treatment. Medical treatment consists of gastric lavage followed by thickened feeds. After lavage, in which the use of alkalis must be avoided owing to the risk of alkalosis, small doses of atropine may be left in the stomach. Good results have been recorded by the use of luminal in doses sufficient to keep the infant drowsy.

In this country the best results have been obtained by Rammstedt's operation: this consists in cutting through the tumour longitudinally from the peritoneal surface as far as the mucous membrane, so that the obstruction is relieved. After operation food should be very gradually increased. Sudden increases usually lead to diarrhoea owing to the fact that during the preceding starvation the absence of the stimulus of food has led to poor secretion of digestive enzymes. Similar intolerance is found in most under-fed babies when the diet is increased too rapidly. The operation has sometimes been followed by diarrhoea with fatty stools (48), which suggests that biliary and possibly pancreatic insufficiency play a part in the disease.

CARCINOMA OF THE STOMACH

Ætiology. Carcinoma of the stomach is rarely seen before the age of thirty, and 60 per cent. of the cases occur between forty and sixty; it is about twice as common in males as females; heredity is not a prominent feature of carcinoma of the stomach. It is equally frequent among the rich and the poor, and is not related to any particular occupation. Much controversy has arisen as to whether carcinoma arises commonly from gastric ulcer; against this view is the fact that duodenal ulcer is very common and yet carcinoma of the duodenum is very rare. In a series of fifty cases of gastric carcinoma, 56 per cent. had a history extending back for a year, but no longer; in 70 per cent. the history was up to two years (57). Hence in most cases, say roughly two thirds, a carcinoma starts *sui generis* (46), though chronic gastritis, and especially polyposis of the stomach, are likely predisposing causes. In the remainder it results from gastric ulcer.

Pathological Anatomy. Carcinoma affects all parts of the stomach, but

in the majority of cases the pylorus is involved, and the disease extends thence to the adjacent parts of the organs, especially along the lesser curvature. If it affects the cardiac end, the œsophagus is generally also invaded. Sometimes the wall of the stomach is uniformly infiltrated and thickened, and the organ, as a whole, is contracted to a small size (*leather-bottle stomach*). With few exceptions, carcinoma of the stomach is in the form of spheroidal carcinoma or cylindrical carcinoma; and the former is much more common. Either variety may be scirrhus from excess of fibrous tissue, or medullary from deficiency of it; and colloid degeneration may take place in either, but is more common in the spheroidal variety. The scirrhus change is the most common. Sarcoma is rare.

Carcinoma begins as an overgrowth of the epithelial cells of the glands of the mucous membrane; the growths project into the submucous tissue, proliferate further, and gradually involve all the coats. The wall of the stomach is thickened and the growth projects so as to narrow considerably the lumen of the stomach. The growth does not invade the duodenum. In later stages it often ulcerates upon the inner surface. The adjacent mucous membrane may show nodular growths of villous processes due to chronic gastritis.

The ulcerative process may erode vessels and lead to hæmorrhage; this is much less often profuse than it is in simple ulcer. Dilatation of the stomach is frequent as a result of *stenosis* caused by a pyloric growth; but a leather-bottle stomach is small. *Adhesion* of the stomach to other organs commonly takes place, as the growth reaches the peritoneal surface, and invasion of the organ with carcinoma may follow. The liver and pancreas are thus frequently attacked, occasionally the spleen or colon. In the last case a *gastro-colic fistula* may result. Carcinoma of the cardiac extremity frequently invades and obstructs the œsophagus.

Secondary deposits occur in various organs, in the peritoneum, in the liver, pancreas, lungs, and adjacent lymph glands. These are the mesenteric, retro-peritoneal, and portal glands; but, as occurs also in œsophageal carcinoma, the cervical lymph glands are sometimes affected quite early.

Symptoms. Clinically there are two groups of cases according to whether the pyloric function is disturbed with undue retention of gastric contents or not.

(1) In the earlier stages of this group the symptoms are chiefly those of dyspepsia. There are loss of appetite and nausea, in the first place, and then sinking, pain after food, and flatulence. The *pain* may be at the epigastrium, or in the position of heartburn. Vomiting is likely to occur earlier in the case when the carcinoma is situate at the pylorus than if it is remote from that point. The vomit consists of food in different stages of digestion, mixed with more or less mucus or streaks of blood. Often the blood mixed with the vomit has the appearance of coffee grounds.

Pain then becomes a more prominent symptom, and if the growth invades neighbouring organs, such as the pancreas, it becomes constant, or arises independently of a meal; it is felt between the shoulders, or in the lumbar region. It is often stabbing and lancinating, but may be boring, burning, gnawing, or tearing. Indications of severe constitutional disturbance set in comparatively early in this type of carcinoma of the stomach. The patient loses flesh, strength, and colour; and in advanced conditions *emaciation* and *anæmia* are extreme. The bowels are mostly constipated. *Melæna* is rare as an early sign, but *occuli blood* (see p. 330) is common.

(2) When the function of the pylorus is not interfered with, the growth is usually, but not always, in the body of the stomach. There may be no symptoms until the growth is far advanced. Pain may then be felt in the back from infiltration of neighbouring structures. But such a growth may bleed continuously, the altered blood being passed in the motions, and the resulting *anæmia* may arouse suspicion of pernicious *anæmia*, when the tumour is impalpable. At the same time there may be progressive *cachexia*.

In general, it may be said that in the majority of cases of carcinoma a *tumour* is discovered at some time or other, but rarely in the first three or four months, and according to some statistics in only 33 per cent. of the cases within the first six months. The position of course varies with the part of the stomach affected. A pyloric tumour is commonly situated in the middle line, or a little to the right, midway between the xiphisternum and the umbilicus. When the stomach is much dilated the tumour is even below the umbilicus. It varies in size from that of a walnut to that of a small orange, and is generally very hard. It is at first freely movable, and descends on inspiration, but in later stages it may contract adhesions and become more fixed. It frequently receives an impulse from the underlying aorta. On percussion it is dull or imperfectly resonant; handling it causes pain.

Occasionally perforation into the peritoneal cavity takes place, and is followed by peritonitis; but the symptoms of this event are often obscure or not distinctive. Carcinoma of the retroperitoneal glands causes œdema of the feet, or the same is brought about by thrombosis of the large veins. Gastro-colic fistula, which is mostly the result of carcinoma spreading from the stomach to the colon, is marked either by undigested contents of the stomach passing directly into the colon, and hence *per rectum*, or by faecal vomiting, the contents of the colon passing into the stomach and hence being vomited.

Death commonly takes place from exhaustion as a result of deficient assimilation of nutriment, or of a rapid spread of secondary growths in the peritoneum with ascites, or in the liver with continued pyrexia. A profuse hæmorrhage or peritonitis, bronchitis, or pneumonia may terminate the scene.

Duration. The illness commonly lasts from six months to two years; two-thirds of the cases last less than eighteen months, and a very small proportion more than two years.

Diagnosis. Carcinoma in its later stages is distinguished from the majority of the diseases of the stomach by the presence of a tumour. Occasionally the diagnosis has been suggested by the discovery of a hard enlarged cervical gland, especially on the left side. If no tumour is discoverable, carcinoma may be confounded with pernicious anæmia, as already indicated, or chronic dyspepsia, including gastritis or peptic ulcer, or purely neuralgic pains may be thought to be due to carcinoma. Exceptionally the tumour of carcinoma may be simulated by the matting and adhesion of parts caused by ulcer. The age of the patient and the relatively short duration of the disease are also important elements in its diagnosis, since carcinoma in most cases is not the result of a previous gastric ulcer.

The X-rays show characteristic appearances. There is an interruption of the shadow due to a bismuth meal by a more or less extensive clear area, or "filling defect," which encroaches upon the shadow by two or more curved or scalloped outlines; this represents the fungating growth projecting into the lumen of the stomach (*see* Plate 28, A). It is tender on pressure, and is constant in shape, taking no part in the peristaltic movements which may be seen elsewhere in the stomach. This interrupted peristalsis may be the earliest sign, before any filling defect is visible. In the case of leather-bottle stomach, the food is seen to fall rapidly through a comparatively narrow tube straight into the duodenum without any peristalsis being visible at all (*see* Plate 28, B). A normal X-ray report was made in 16 per cent. of cases (57).

Examination of the stomach contents in the early morning should be undertaken, after the patient has taken two teaspoonfuls of charcoal in milk the night before (49). The presence of visible blood, either fresh or altered, is suggestive of carcinoma, especially if it is found on more than one occasion, while the presence of charcoal indicates delay in emptying. In 47 per cent. of cases blood was present in the resting juice, and in 87 per cent. there was no free HCl (57). A persistent oozing of blood is characteristic of carcinoma, while an occasional

profuse hæmorrhage is more probably the result of ulcer. Coffee-ground vomit is seen in both.

After washing out the stomach a test meal may then be given. The presence of lactic acid in the test meal suggests carcinoma of the stomach. There was achlorhydria in 64 per cent. of cases; so that free HCl in varying amount is commonly met with. There may even be hyperchlorhydria (57). But usually there is great diminution in the "active HCl" and in the amount of "free HCl." In some cases the mineral chloride is low, due to an associated chronic gastritis. In other cases the mineral chloride is high, which suggests that the HCl has been neutralised by the serum exuding from the growth. Only 46 per cent. of cases showed delayed emptying of the stomach. Blood was present at some time in 64 per cent., and in the remaining 36 per cent. it was present in varying amounts in the stools when examined for occult blood. Hence the absence of blood, both in the test meal and stools, will nearly always exclude gastric carcinoma, but the present writer had a case in a woman of forty, proved by operation, with no blood in the test meal and stools, though there was achlorhydria and a large filling defect by X-rays.

Prognosis. This is very unfavourable, as death is inevitable unless the growth and all infected glands can be entirely removed.

Treatment. In suspected early cases laparotomy should be advised, as removal of the growth is almost the only possible method of cure. It is usually too late to do this by the time a lump can be felt, owing to spreading of the growth and involvement of the lymphatic glands. Gastro-jejunostomy may be performed as a palliative measure. Deep X-ray therapy may be tried.

If dilatation is a prominent symptom, and large quantities of food are vomited every few days, relief may be temporarily afforded by washing out the stomach daily (see p. 352), or the patient may be instructed to pass a tube when pain is felt, relief sometimes being obtained by this simple measure alone. Otherwise the measures described under chronic dyspepsia may be used.

Benign Tumours of the Stomach.—These include *adenoma*, *myoma*, *accessory pancreas*, *lipoma*, *fibro-lipoma*, *lymph-adenoma*, and *cysts*. They are quite infrequent. The first three are the least uncommon, and they occasionally cause symptoms by obstructing the pylorus. In other cases the symptoms will depend on the size and position of the growth.

CONSTIPATION

The healthy action of the bowels depends on a sufficient supply of food, the waste of which forms the material for the fæces; a natural secretion of intestinal juices; and an intestinal muscular system readily stimulated and strong enough to force on the fæces from point to point. This action, however, varies in different individuals, who may still all be healthy. Most persons have an action of the bowels once a day, but others twice a day, and some only every other day. Constipation is the retention of fæces for longer than the normal period of twenty-four hours, or in some persons two days; and is due to delay (1) in the general movement along the large intestine (*colonic stasis*), or (2) in the evacuation of the pelvic colon and rectum (*dyschezia*), or in both the processes together.

1. The general movement of fæces along the intestinal canal is purely involuntary, and is dependent upon the adequate muscular power of the intestinal wall, properly stimulated to action by suitable food. A weak musculature may be a hereditary failing, or it may supervene in later life as a cause of senile constipation. A temporary weakness occurs in fevers and acute illnesses, and may result from anæmia, chlorosis, rickets, and diseases involving nervous depression, such as melancholia, neurasthenia, etc. Locally it may be due to flatulent distension, and to catarrh of the mucous membrane.

The stimulus to the bowel comes chiefly from the food ; and this may be insufficient in quantity, or too dry, or deficient in mechanical stimuli, of which the cellulose of vegetable substances is the most important. It appears also that in some individuals unusual powers of digestion and absorption on the part of the intestines may leave so little residue that evacuations must be infrequent ; a condition that is known as "greedy colon." In many gastric disorders, especially where vomiting is frequent, constipation occurs. Further, the reflex action of the bowel may be directly inhibited by painful local affections of an inflammatory or traumatic nature in the pelvis or abdomen.

Colonic stasis can only be diagnosed by examining the intestines after an opaque meal has been given. Under ordinary circumstances, at the end of four hours the stomach is empty and the food is collecting at the end of the ileum. The taking of a second meal causes special activity at the end of the ileum and in the colon, so that the intestinal contents move forward rapidly (*gastro-ileal and gastro-colic reflexes*) (50). The opaque meal has usually left the ileum four hours after it has completely disappeared from the stomach ; but ileal stasis can only be diagnosed with safety if no trace of the meal has entered the cæcum six hours after taking it, or if the bulk of the meal is still at the end of the ileum nine hours after the meal is taken if the stomach is known to have emptied itself in three or four hours. Normally the opaque meal reaches the rectum in twenty-four hours. *Colonic stasis* will exist if at the end of this time it is still entirely in the cæcum and ascending colon, or if the splenic flexure is first reached in twenty-four hours, but the opaque meal still remains in the transverse colon forty-eight hours after the meal. If colonic stasis is severe, there will also be delay in the passage of the intestinal contents through the ileo-cæcal valve (*ileal stasis*). Ileal stasis may occur without colonic stasis, especially in cases of sub-acute appendicitis (*controlling appendix*).

2. The desire to defæcate is caused by the entry into the rectum of the fæces which have accumulated in the pelvic colon during twenty-four hours, and this is brought about reflexly by the stimulus of eating breakfast, or of getting up, or of some other daily recurring function.

The defect in the final process of defæcation, that is, in the passage of fæces into the rectum, and the final evacuation, is a common cause of so-called habitual constipation. It is called by Hurst *dyschezia* (χέζω, I ease myself). The performance of this function is dependent upon a stimulus conveyed from the rectum, and the response upon the part of the pelvic colon. In well-regulated persons the stimulus arises at a given time every day, and if allowed to operate an evacuation is the result. If the stimulus is disregarded and the desire to go to stool is repressed, the reflex is likely to be less active on a subsequent occasion, and in course of time the stimulus may fail to be felt. Thus the repression of the desire and the disregard of the sensation are common causes of constipation. Want of time in the case of persons hurrying to business, false modesty in large houses, or in girls' schools, inadequate supply of accommodation in large establishments, mere laziness in many people, contribute to this, and lead to a postponement of the process until the regular habit is entirely given up, the fæces are retained for two or three days or even a week, and then evacuation can only be secured by the use of aperient drugs or an enema.

Another cause of dyschezia is weakness of the voluntary muscles which compress the abdominal contents, and thus assist in the passage of fæces from the colon into the rectum, and from the rectum through the anal passage. These are the abdominal expiratory muscles, the diaphragm, and the levator ani and other muscles of the pelvic floor.

Dyschezia can be diagnosed if the greater part of the opaque meal has reached the pelvic colon and rectum twenty-four hours after it has been taken, and if, in spite of this, there is no desire to defæcate.

In any part of the large intestine delay may be caused by mechanical obstacles

to the passage of the fæces, such as compression or kinking of the colon, hard fæcal masses, stricture by growth, a retroverted uterus, spasm of the sphincter ani, and spasm of the colon, a condition described as *enterospasm*. Some of these conditions in a higher degree lead to complete obstruction.

Symptoms. If left to themselves the bowels only act at intervals of two, three, four, or more days; the colon or rectum becomes loaded with hard, round masses of fæcal matter (*scybala*), generally rather pale, which are welded together into masses. The desire to go to stool perhaps at first only results in ineffectual straining efforts; but finally some scybala are passed, and the same may be repeated two or three times within a few hours, till the lower bowel is emptied. After this the bowel is inactive for another period of several days. During the retention the patient may suffer various inconveniences. Locally there may be a sense of fulness in the perineum, or pruritus ani; and the hæmorrhoidal veins may swell, and possibly hæmorrhoids may be caused. Sometimes there is pain down the thigh from pressure of the fæcal masses on the nerves in the pelvis; moderate distension of the abdomen often occurs, with perhaps flatulence and eructations; the tongue is often furred, whitish or dirty brown, and the breath may be foul. Some patients feel languid, confused, wanting in vigour or freshness, and have actual headache, or even a great deal of mental depression. These and many other symptoms are attributed by some to the retarded progress of the bowel contents or *intestinal stasis* (see p. 360). But it must be noted that often the more habitual the constipation, the less is the general disturbance; and many are not conscious of having anything the matter with them though their last evacuation was many days before.

Where the fæces are retained in the rectum the latter becomes enormously dilated to accommodate them. The scybalous condition of the fæces is explained by their retention in the colon, during which there is time for the absorption of most of the liquid contained in them. Even when the rectum is distended with scybalous masses, some fæcal fluid may escape from the anus, or a secretion of mucus may be excited, and the discharge of these liquids may stimulate a diarrhœa. A more extensive catarrhal colitis, and stercoral ulcers, may also result from constipation.

The accumulation of fæcal matter in the pelvic colon may be such that it forms a large tumour in the lower part of the abdomen, of which the distinguishing feature is the fact that it can be indented by firm pressure with the finger.

Treatment. In general it may be said that colonic stasis requires treatment by means of diet, and in severer degrees by massage, abdominal exercises and drugs, and dyschezia by persuasion and exercises, and in severer degrees by graduated enemas. It must be remembered that some patients do well with an evacuation every second or third day.

The patient should make a regular and not a hurried daily visit to the closet whether he feels any desire or not at the time; and this should be continued as a habit for the rest of life, but it may take months before its good effects come into full operation. In dyschezia the squatting position should be adopted.

The diet should be modified so as to include a sufficiency of vegetables, fruit, fresh or preserved, or salad with salad oil; brown bread, wholemeal bread, or oatmeal porridge sometimes supplies the desired stimulus to the bowel. The diet also should be liquid enough, and with some a daily evacuation is ensured by drinking a tumblerful of cold water or eating an apple before breakfast. A teaspoonful or two of the non-absorbable powdered agar-agar added to porridge, potatoes or stewed fruit is valuable in cases of greedy colon.

To those of sedentary habits walking exercise, fencing, horse-riding, or driving is often of benefit, or the abdominal muscles may be specially exercised by Swedish exercises and massage carried out along the line of the colon as indicated by X-rays after an opaque meal. The pelvic floor in women may be exercised by

getting the patient to draw in the anus thirty times morning and evening, as if to prevent the escape of flatus.

But with all this it may be still necessary to have recourse to drugs, and a careful selection is requisite. As a rule, very active or drastic purgatives must be avoided; they produce abundant liquid motions, from the effect of which the intestinal muscle is completely exhausted, and consequently no further evacuation takes place for days afterwards. But it has already been shown that constipation depends on deficiency of peristaltic action, and hence over-stimulation and exhaustion are especially to be avoided. From this point of view much advantage is gained by combining with the ordinary laxatives such drugs as have a tonic effect upon the intestinal muscle. These are especially *nux vomica* and iron. *Senna* pods, soaked some hours in cold water and drunk at night, are a valuable laxative. *Cascara sagrada* may be given every night in doses of 30 or 40 minims of the liquid extract combined with syrup of ginger, or 2 or 3 grains of the solid extract in pill. Pure liquid paraffin may be given in doses of $\frac{1}{2}$ ounce to 1 ounce once or twice daily according to the necessities of the case. An efficient combination is that of aloin with extract of *nux vomica*, 1 grain or $1\frac{1}{2}$ grains of the former with $\frac{1}{4}$ or $\frac{1}{2}$ grain of the latter, given in the morning before breakfast; $\frac{1}{4}$ grain of extract of *belladonna* or $\frac{1}{2}$ grain of *ippecacuanha* is sometimes usefully added. Sulphate of iron (1 grain) with aloin and *nux vomica* is also very useful. If a daily pill is insufficient, two or even three pills may be taken; but in either case the essence of the treatment is that active purgation should be avoided, and directly this seems likely to be produced the three pills each day must be reduced to two, or the two to one; and ultimately the bowels will act without any assistance whatever. In some acute abdominal conditions and after abdominal operations *eserine salicylate* or *pituirrin* may be injected subcutaneously. The natural saline waters, when procurable, are of value, such as *Rubinat*, *Püllna*, *Hunyádi Janos* (containing the sulphates of magnesium and sodium), and *Carlsbad* (mainly sulphate of sodium); the patient may take from a wineglassful to half a tumblerful before breakfast. *Carlsbad* salts extracted from the water of the different springs, or sulphate of sodium itself, may also be given—a teaspoonful is dissolved in half a tumblerful of hot water, and drunk before breakfast. Enemas of cold water are often necessary at the beginning of treatment when there is accumulation of *fæces* in the bowel, and particularly in the rectum, which is below the point of direct operation of aperients. When a large accumulation of *fæces* has taken place, the enema may have to be assisted by the use of the finger; for some days after this the enema may be used to supply the stimulus until a more natural method is established. In *dyschezia* not curable by persuasion and exercises graduated glycerine enemas should be tried, beginning with 1 ounce and gradually replacing more and more of the glycerine by water on successive days.

ALIMENTARY TOXÆMIA

By alimentary toxæmia is meant the absorption into the blood of toxins or poisons derived from the alimentary canal. The belief has been gaining ground that a great many symptoms, pathological conditions, and even definite diseases are due to this toxæmia. But many difficulties will have to be overcome before this theory can be put on a thoroughly scientific basis. At present one cannot say much more than that treatment based upon the hypothesis has often been successful. The steps between the cause and the result are not always easy to trace.

Firstly, the origins of the toxins may be organisms introduced from without, as in the case of oral sepsis already referred to (*see p. 321*), in which disease may be produced either by streptococci entering the blood stream or by the constant swallowing of these micro-organisms which come from infected dental

sockets. These may settle down in various parts of the alimentary tract, and produce infections there. Recently some cases of rheumatoid arthritis and osteo-arthritis have been ascribed to this cause. Secondly, food may actually contain poisons, or an excessive proportion of proteins which may decompose, or carbohydrates which may undergo fermentation; and, thirdly, food, or rather faecal matter, may be retained, as the result of habitual constipation, sufficiently long to undergo bacterial or chemical changes with the production of toxins, or poisonous chemical substances (*enterostasis*).

The complicated processes of digestion which take place in the alimentary canal from stomach to rectum inclusive, and the chances of delay and disturbance offered by such an elongated cavity, seem to provide abundant opportunity for the formation of chemical poisons, or toxins, and their passage into the circulation. But at the outset it is possible that it is not only a question of the occurrence of new poisons or toxins, but of the breaking down of the mechanisms by which normally poisons in the alimentary canal or elsewhere are prevented from reaching the blood. These are the digestive secretions, the mucous membranes and their mucus, the antitoxic action of the liver, and possibly the action of the thyroid gland.

But it appears to be uncertain whether at all, or in what circumstances, the bacteria usually found in the intestine do any material harm; and with regard to chemical substances there is still much to be learned, some attaching importance to the formation of indol, skatol, and phenol, and of ethereal sulphates in excess, while others, as Mellanby, see more danger in the amines produced by the splitting off of CO_2 from the proteolytic amino-acids by intestinal bacteria.

Cases of food-poisoning, in which decomposing food containing specific bacilli is ingested and symptoms result therefrom, need no comment.

Gout and allied conditions are attributed to the prolonged use of food containing a high proportion of proteins, but it is still open to question whether this is because the proteins decompose readily; whether micro-organisms have any relation to them; or whether bacterial toxins, or other chemical compounds, such as purins, cause the mischief. Similarly an excess of carbohydrates may, in infants, cause a toxic condition in which fever, sickness, diarrhoea with acid green stools, and abdominal distension are present. Some cutaneous eruptions appear to depend upon gastro-intestinal irregularities—for instance, acute urticaria after shell-fish, whether this is due to direct poisoning or is an instance of anaphylaxis, as some believe.

Interest has also centred around the third factor, namely, chronic constipation or enterostasis, causing faecal retention, to which Sir Arbuthnot Lane has attributed so many evil results. His contention is that from improper feeding in early life and from the maintenance of the erect posture the intestines tend to fall, that peritoneal adhesions are formed in various parts to support them, that subsequently with continued retention, and excessive weight of the retained faecal matter, kinks are formed at the end of the ileum and in the duodenum, which increase retention and lead to dilatation of the parts above, while there is a general proptosis of all the organs. From the faecal matter thus retained in consequence of this intestinal stasis toxins are formed which act prejudicially both locally and generally. Among the local results are said to be the following: appendicitis, duodenal ulcer, spasm of the pylorus, gastric dilatation, gastric ulcer, gastric carcinoma, and pyorrhoea alveolaris.

In the general condition of the patient the toxæmia caused by this intestinal stasis is recognised by him in every tissue of the body: cold hands, defective circulation, dusky hue of face, pigmentation of the face and body, dull sclerotic and œdema of the conjunctiva, mental dulness, depression, headache, insomnia, incapacity for physical or mental exertion, neuralgia. In the female especially, he states, the effects are pernicious: loss of fat occurs, the kidneys

fall, the uterus is retroflexed, cystic disease and carcinoma of the breast occur, and infection of the genito-urinary tract readily takes place.

It must, however, be admitted that other observers do not believe that chronic intestinal stasis does produce such evil results; they believe that the symptoms complained of by such patients are really due to neurasthenia, which has developed from the habit of introspection, and in particular of constantly paying too much attention to the movements of their bowels.

Prof. Arthur Keith holds different views from those of Sir Arbuthnot Lane with regard to the origin of stasis in the bowel. As the result of observations with X-rays on the movements of the stomach and intestine, and of microscopical researches on Auerbach's plexus and associated structures in the bowel, he puts forward the theory that the peristaltic movements start from separate points in the intestinal canal, which are, in relation to such movements, divisible into the following sections:—duodenal, jejuno-ileal, proximal colic, and distal colic. In each of these sections peristalsis has been observed to be more active at the upper end, and less active as it proceeds downwards, so that at the lower end a condition allied to sphincter action is assumed. Keith recognises in the upper end of each of these sections neuro-muscular tissue analogous to the sino-auricular node of the heart, which he therefore calls *nodal tissue*; and he looks upon the mesenteric (Auerbach's) plexus as the analogue of the auriculo-ventricular bundle. He thinks that an alteration in the orderly transmission of impulses along either of the sections from its upper nodal tissue downwards will account for the enterostasis in the section concerned without the necessity for the adhesions, bands and kinks described by Lane. He is disposed to believe that similar neuro-muscular tissue in the œsophagus and stomach respectively may function in the same way.

A very thorough treatment on medical lines by diet, purgatives, and other measures, as described under "Constipation," should be carried out.

DIARRHŒA

By diarrhœa is meant the passage of motions more often and of looser consistence than is normal. It is the result of excessive peristaltic action, and of excessive intestinal secretion or deficient absorption. Its causes may be classified as follows: (1) *Gastrogenous*. There is often hypochlorhydria, and the administration of 20 or 30 minims acid. hydrochlor. dil. three times a day may check it. Diarrhœa may follow gastro-jejuno-stomy. (2) Infection of the *small intestine*, such as occurs in catarrhal enteritis, typhoid fever and tuberculosis, may be responsible. In tuberculosis the looseness and undigested character of the motions may be due to deficient absorption. There is also the diarrhœa of cœliac disease, chronic pancreatitis, sprue and lardaceous disease. (3) In the *colon and rectum* the causes of diarrhœa are numerous, including the dysenteries, ulcerative colitis, acute colitis often associated with septicæmias, *e.g.* pneumococcal, the colitis of chronic nephritis, malignant disease, the irritation which follows the abuse of purgatives and enemas. (4) *Reflex diarrhœas* result from cholecystitis and appendicitis. (5) The *nervous system* may cause diarrhœa through emotion or hysteria, and there is a rare form of diarrhœa due to tabes. (6) There is a *mixed* group, which includes the diarrhœa of Graves' disease and excess of insulin.

It must be remembered that the frequent discharge of liquids in small quantities does not of itself show that the canal of the bowel is free. Thus intussusception which partly obstructs the gut is accompanied by the passage of mucus and blood; fæcal fluid mixed with mucus may find a way past very large masses of impacted fæces; and, lastly, even a distinctly contracted intestine may allow some of the thin liquid which collects above the obstruction to pass through and simulate a diarrhœa. These are called *spurious diarrhœas*.

Varieties. Diarrhœa has received different names according to the nature of the matters passed. Thus we have *choleraic* diarrhœa, in which the stools are profuse and watery, or like the rice-water stools of cholera; *dysenteric* diarrhœa, in which mucus is largely present, and perhaps blood; *lienteric* diarrhœa, where taking food into the stomach produces a motion: this is probably due to an increase in the normal gastro-colic reflex (50); and *bilious* diarrhœa, when the discharges are deeply stained with a brown or greenish-brown colour, which is due not so much to any increase in the quantity of bile secreted as to the fact that the contents of the duodenum and jejunum stained with bile have been hurried through the alimentary canal without giving time for the natural reabsorption of the altered bile pigment (urobilin). *Colliquative* diarrhœa is a term applied to the profuse, exhausting, and intractable discharges which occur in the last stages of phthisis. A *critical diarrhœa* is an old term for a diarrhœa that accompanies the termination of a pneumonia by crisis; it is probably due to an associated entero-colitis.

Treatment. This must depend upon the cause, or the associated condition. In most cases not of a specific nature, the treatment described under Enteritis may be employed. Lienteric diarrhœa, which depends upon an exaggerated intestinal reflex, may be treated with full doses of potassium bromide.

HÆMORRHAGE FROM THE BOWEL

The passage of blood *per rectum* has already been noticed as occurring in enteric fever, and in ulcer of the stomach and of the duodenum. It also results from other ulcerations, as dysentery and ulcerative colitis, from intussusception, from carcinoma of the sigmoid or rectum, from conditions of intense congestion, from embolism or thrombosis of mesenteric vessels, and from purpura and other conditions of blood disease. The way in which the blood is passed may give a clue as to the point whence it comes. In bleeding from gastric or duodenal ulcers the blood is considerably altered by the secretions, and forms a black, tarry, semi-liquid or treacly mass (*melæna*); in hæmorrhage from typhoid ulcers the blood is equally unmixed with fæces, but brighter red and more fluid than in the former case, from the action of the alkaline contents; the blood in dysentery is in streaks or small clots mixed up with mucus or pus, or thin fæcal matter, though from time to time small quantities of pure blood may be passed. Large quantities of blood may be lost from piles, or from an ulcer of the rectum. Here the bleeding is generally caused by the act of defæcation, the blood either streaking one side of the solid fæcal mass, or coming more or less pure in drops or streams after the motion is evacuated. In scorbutic, purpuric, and hæmorrhagic conditions (scurvy, purpura hæmorrhagica, acute yellow atrophy of the liver, malignant variola) blood comes from the rectum more or less mixed with fæces, or pure, according to the part of the intestine yielding it, or the freedom with which it escapes. The diagnosis of small quantities of blood has already been considered (see p. 330). The **Treatment** of hæmorrhage is described with the various diseases which may cause it.

COLIC

The term *colic*, though derived from the word *colon*, means a spasmodic abdominal pain of visceral origin. It is due to a violent peristaltic contraction which is held up by some obstruction during its course down the alimentary canal. Colic may occur in the ureter (renal colic), the bile ducts (biliary or hepatic colic), or the intestines (intestinal colic).

Ætiology. A common cause of intestinal colic is irritating and unsuitable ingesta, such as pork, cheese, high game, shell-fish, ices, etc. In children, colic is a common result of indigestible food, or even simple excess. With these may

be classed the more active purgatives. On the other hand, constipation is often associated with colic, and this is markedly so in the colic due to lead poisoning, whether acute or chronic (*see* Lead Poisoning). Some cases may perhaps be referred to a purely nervous source—for instance, the severe pain of gastric crisis in tabes dorsalis. Lastly, mechanical and acute inflammatory lesions of the bowel, such as strangulation and intussusception, lead to severe pains, which are partly or wholly due to muscular contraction. The term *colic* is, however, generally reserved for conditions in which there is no structural or inflammatory change.

Symptoms. The important symptom is pain, which is situate about the umbilicus, but may move about other parts of the abdomen. This pain is often relieved by pressure, but sometimes there is tenderness. The abdomen is either drawn in, and the abdominal muscles are contracted, or the belly is distended from the presence of flatus. When flatus is present borborygmi are produced by its movements, as it is driven on by the varying intestinal spasm.

The pain may be so severe as to cause much collapse, with profuse clammy sweat and small feeble pulse. Sometimes there is vomiting; often there is constipation; on the other hand, some ingesta, which cause colic, set up active diarrhœa with brown watery stools, and mucus after a time. Here the colic is associated with a definite, though slight, enteritis. The more active purgatives also produce griping and “colicky” pains, which are commonly diminished after each evacuation.

Diagnosis. Any of the colics may be confounded with the pains of any acute inflammation in the abdomen or acute intestinal obstruction. The characteristics are the restlessness of the patient, who may throw his arms about; his flexed position, since pressure on the abdomen usually relieves the pain; while rigidity is usual during the pain, there is flaccidity between whiles; the pain may shoot in a characteristic direction, especially in renal and biliary colic.

Treatment. Obviously, cases of severe abdominal pain must be treated with much caution. If the pain is certainly due to irritating ingesta, relief generally follows the exhibition of purgatives, such as an ounce of castor oil with 15 minims of tr. opii, or $\frac{1}{2}$ ounce of magnesium sulphate with $\frac{1}{2}$ drachm of tr. hyoscyami, or 5 grains of calomel; and a similar line of treatment is used in lead colic (*see* Lead Poisoning). A warm water or castor oil enema may also help, and hot fomentations or a hot-water bottle should be applied to the abdomen. Papaverine hydrochloride $\frac{1}{2}$ to $1\frac{1}{2}$ grain by mouth may also be tried as an anti-spasmodic. If there is any likelihood that appendicitis, peritonitis or obstruction may be present, purgatives should be avoided; and the question of treatment by operation must be considered.

ENTERITIS

There are several conditions, affecting different parts of the alimentary canal, which may properly be termed enteritis, or inflammation of the intestine. For instance, the catarrhal process, of which some forms of diarrhœa are the result; tuberculous and typhoid ulcerations in the ileum; the ulcerative inflammation of the colon, known as dysentery; and the acute changes set up by intussusception and strangulations, are all, in fact, enteritis. But a large number of these have already received distinctive names; others are only secondary conditions, which produce few symptoms beyond those of the primary disorder; and in others, again, inflammation of the coats of the intestine involves a peritonitis, which throws the symptoms due to the mucous inflammation completely into the shade. Thus the number of cases which require separate description as enteritis is but a small one, though it is probable that a fair consideration of the pathological side of many of our intestinal cases, such as diarrhœa, would show that the name might be justly used more often.

The following forms of enteritis will be here described: *catarrhal enteritis*,

infantile enteritis, food poisoning, sprue, diphtheritic enteritis, and phlegmonous enteritis.

CATARRHAL ENTERITIS

(*Intestinal Catarrh*)

Anything which irritates the mucous membrane of the intestine may set up catarrh, such as unsuitable food, certain poisons, and purgative drugs. Catarrh is also ascribed sometimes to chill; but a much more potent factor in its production is excessive heat, and it is always more prevalent in the hot weather of summer and autumn than in the remaining part of the year. This frequency in the summer concerns people of all ages, but infants are especially attacked, as described later. Passive congestion in cardiac and hepatic disease may lead to catarrh of the intestines.

Morbid Anatomy. The changes in the mucous membrane of the intestine are similar to those in other mucous surfaces of the body. The tissues are more vascular, and become swollen. The epithelial cells, including those of Lieberkühn's glands, are swollen, cloudy, and become detached, forming mucus, which is present in large quantity, and cellular infiltration takes place in the inter-tubular tissue. In more advanced cases the solitary follicles are enlarged, and they may become eroded and produce small ulcers (*follicular enteritis*). In some cases also ulcerations occur in other parts of the mucous membrane, and the secretions may consist of muco-pus, or even pus. As a rule, the inflammation subsides, but it may lapse into a *chronic* condition, with more prominent changes in the mucous membrane. Sometimes there is considerable thickening, with slaty discoloration of the surface; often—especially in the chronic catarrh of infants—there is atrophy of the mucous membrane, involving the glandular layer, but leaving the muscular layer of the mucous membrane, and the sub-mucous tissue, intact.

Symptoms. The chief symptom of enteritis is diarrhoea, or the frequent passage of motions loose or liquid in consistence. This symptom is due not only to the alteration in the secretions poured into the intestinal canal, but also, and largely, to the increased peristaltic movements which the irritation of the mucous membrane calls forth. The condition of the fæces varies much: they are generally at first abundant, liquid, and brownish in colour, with flakes or lumps of more solid matter; but they soon become paler, or, it may be, yellowish or sometimes green. In consistence they are often quite watery, or perhaps slimy, or they contain lumps of stained mucus. Under the microscope there are particles of undigested food, meat fibre, starch granules, and fat, with crystals of ammonium magnesium phosphate, epithelial and pus cells, and bacteria. The bowels may be moved from two or three times a day to ten, twelve, or more.

Colicky pain is often present, which precedes the passage of the motions. Actual tenderness is sometimes present. Borborygmi from time to time accompany the more active intestinal movements. The temperature is variable. Frequently the appetite is lost, the patient complains of thirst, the mouth is dry, the tongue is slightly furred, and a considerable degree of bodily weakness results when the diarrhoea is excessive. A very sudden and acute attack may begin with vomiting.

In most cases the symptoms pass off in the course of a few days; the diarrhoea may cease suddenly, leaving a long interval before the bowels are again opened, or the motions may gradually become less frequent, gaining a firmer and firmer consistence. If the complaint becomes chronic, the patient is troubled with three or four evacuations daily of watery mucus, with occasional griping pains. The imperfect digestion and absorption of food may lead to considerable loss of nutrition.

The disturbances of enteritis frequently extend to the large intestine, so that strictly an *entero-colitis* results. When they can be discriminated catarrh of the *small* intestine is more likely to be present if the stomach is at the same time involved; it is less likely to be accompanied by diarrhoea, which must depend finally upon the action of the large intestine. The evacuations often contain bile and undigested food; and mucus, if present, is more intimately mixed with the *fæces*. In catarrh of the *large* intestine the mucus occurs in separate masses; muco-pus or pus itself may be recognised. As catarrh approaches the *rectum* tenesmus is more likely to be a symptom.

Treatment. The patient should remain in bed and be kept warm. In severe cases it will be advisable to keep the patient without food for the first twenty-four hours; but as much water should be given as the patient wishes to drink. Later gruel, arrowroot, beef tea, or mutton broth, with rusk or toast, milk and soda water, or milk and lime water in small quantities at a time, should take the place of the ordinary meals. They should not be given too hot. It is a good plan to begin treatment with a purgative. For this purpose a single dose of castor oil may suffice, or one of compound rhubarb powder or of calomel. But generally, by the time the case comes under treatment, there has been a free evacuation, and it is desirable to check the excessive peristalsis and abundant discharge as well as to relieve pain. The tincture of opium may be given in doses of 5 minims every four hours, combined with an astringent such as hæmatoxylum, catechu, tannigen (5 grains in cachet), the aromatic chalk powder, or dilute sulphuric acid. Bismuth carbonate and bismuth salicylate are also of value, and may be given with opium. If the griping is very severe, morphia may be injected subcutaneously. If the diarrhoea is obstinate and exhausting, an enema of 2 ounces of starch containing 15 minims of laudanum may often be used with success.

INFANTILE ENTERITIS

Infants are subject to diarrhoea from a number of causes. (1) In the neuro-pathic infant, abnormally irritable to all stimuli, increased peristalsis is readily produced, with resulting diarrhoea, often aggravated by excessive feeding given in an attempt to appease his cries. (2) Apart from such children, overfeeding leads to dyspepsia, associated with wind and colic. Loss of appetite and restlessness precede an attack of acute diarrhoea. Such overfeeding is especially likely to occur in hot weather when milk is given to quench the child's thirst. (3) In artificially fed babies, excess of sugar or fat in the food leads to fermentation in the bowel and an explosive diarrhoea. The attack is often preceded by an abnormally rapid gain in weight. Composition of the food is less likely to be important in the case of breast-fed babies; though immediately after birth, diarrhoea, with acid green stools, is not seldom encountered and is cured by giving extra protein. (4) Diarrhoea is often a symptom of a general infection. (5) Stale and contaminated milk may cause fermentation in the intestines, with resulting diarrhoea. Infection of the alimentary tract with specific organisms is probably a rare cause, though small epidemics undoubtedly occur from time to time.

(6) The incidence of so-called *summer diarrhoea* (epidemic infantile diarrhoea) shows a close relationship to the atmospheric temperature. Tolerance to food is diminished in most infants under conditions of prolonged rise of temperature, and alimentary reflexes are exaggerated. The intake of milk is often mistakenly increased in order to meet the demands of thirst, instead of reduced at a time when the body needs less food. Food tends to be more contaminated by organisms which thrive at a higher temperature and which are more readily conveyed to it by flies. Fermentation, already begun before administration, continues in the alimentary tract, unless the organisms are killed by careful sterilization of the food. Restlessness and broken sleep decrease the infant's

resistance. A number of breast-fed babies are usually affected, but in artificially-fed infants, the incidence is very much higher, and the affection tends to be much more severe; this will readily be understood from what has already been said. Many of the babies on artificial foods have already been suffering from dyspepsia; tolerance in these infants is already low, and resistance to original infections or to super-added ones is further decreased.

Symptoms range from those of a mild dyspepsia to those of intoxication—a state closely resembling that of the late stages of tuberculous meningitis, except that if the child is disturbed, for a time its reactions appear to be almost normal. A high temperature is the rule at the onset; later, it often falls. Often there is air-hunger associated with the ketosis. Loss of fluid causes a depressed anterior fontanelle, and dry, inelastic, wrinkled skin, especially over the abdomen. Broncho-pneumonia is common.

Prevention. Avoidance of over-feeding and too frequent feeding is of great importance. In artificially-fed babies, too rapid a gain in weight is often associated with excessive intake of carbohydrate and fat, which should be avoided. In hot weather, the total intake of food should be reduced, boiled water being given to quench thirst. Milk should be as fresh as possible and sterilised or pasteurised before use. If a refrigerator is available, the day's supply of milk should be placed in it and warmed only immediately before use. When there is reason to doubt the quality of the milk, one of the preparations of dried milk should be used. All bottles, containers and teats should be scrupulously clean, kept covered to prevent the access of flies and scalded before use. Ventilation and temperature of the room and the provision of suitable clothing for the infant require constant supervision (*see also* Infant Feeding).

Treatment. If the diarrhoea is not severe, a dose of castor oil may be of advantage in eliminating the fermenting contents of the bowel. Food should be withheld for twelve to twenty-four hours, boiled water being given freely. After this interval, if accompanying vomiting has ceased, food may be gradually resumed, several days being taken before full diet is allowed, any previous errors in diet being corrected. When diarrhoea is a symptom of parenteral infection, the amount of food should be reduced, milk being peptonised and water given freely. Improvement in the diarrhoea is only to be expected with improvement in the infective process. In neuropathic infants, small doses of chloral combined with one or two minims of the tincture of belladonna may be of considerable help. The temperature of the child's environment should be kept as constant as possible. Every care must be taken to minimise the risk of cross-infection from parents and nurses and from other sick infants. In mild cases, no other treatment may be required, but if the diarrhoea continues gentle washing of the stomach and bowel with warm Ringer's solution may be of great value. If the stomach is washed gently and pressures of over one foot are avoided, the process is not greatly distressing, and after a time it will usually be found that the fluid passes freely through the pylorus. Half a pint may be allowed to run through in this manner. The child should then be given a dose of chloral and allowed to sleep; a diluted feed may then be retained. In more severe cases and in intoxication, if the above measures fail it is probably best to resort to feeding by a continuous intravenous drip of 5 per cent. glucose in 0.45 per cent. solution of sodium chloride. It is usually well to initiate this treatment with a transfusion which can be given through the same cannula. The rate of flow should average about 130 c.c. per kilo of body weight in the twenty-four hours. The appearance of oedema usually means that the flow has been too rapid. Expert supervision is absolutely essential and the treatment should not be attempted except under such conditions. If treatment must be given in the home, loss of fluid may be met by subcutaneous or intra-peritoneal injections. Symptoms of collapse may be met by brandy (M. x.), diluted and given by mouth, or by injections of strychnine (gr. 1/200).

FOOD POISONING

By far the commonest cause of acute food poisoning in England is infection by the *Salmonella* group of bacilli, and of these *B. ærtryche* (four types) accounted for three-quarters of the cases ; this bacillus causes a low death rate, *e.g.* about 1 per cent., probably because it has but low invasive powers. Next in frequency comes *B. enteritidis* of Gaertner, which causes a more serious infection. *B. suipestifer* has a low virulence for man and is a rare cause, though it is commonly met with in pigs. These living bacilli gain access in warm weather to food such as "made up" meat, cheese, fish, crabs, mussels and milk products, and even potatoes and duck's eggs (54). However the salmonella toxins are also poisonous, and they may be present in tinned foods, even when the bacilli themselves have been destroyed ; these toxins or *ptomaines* accounted for 17 per cent. of cases. Paratyphoid bacilli are probably not a cause of food poisoning ; but dysentery bacilli were found in 4 per cent. of cases ; an epidemic of dysentery (Sonne) recently occurred (55). The *B. botulinus*, which does not produce symptoms of enteritis, has been found chiefly in sausages made from liver and blood in Germany, and in tinned fruit and vegetables in the United States. Its spores are widely diffused in nature and the bacillus grows anaerobically, producing a toxin which is a very powerful poison, but which is easily destroyed by a temperature of 80° C. (53).

Symptoms. The symptoms of "Gaertner" and "ærtryche" come on as a rule within from six to twelve hours after eating the food, and consist of vomiting, diarrhœa, colicky pains, numbness, and weakness, with perhaps albuminuria, catarrhal pneumonia, and cutaneous lesions, such as herpes, erythema, urticaria, and petechial hæmorrhages. In the less acute and more prolonged cases there may be a close resemblance to typhoid, or paratyphoid, fever. The cases are sometimes fatal, and the autopsies have shown acute gastro-enteritis, sometimes with hæmorrhages, swelling of Peyer's patches, enlarged spleen, and congestion of the liver and kidneys. The bacilli may be isolated from the blood, bowels, or solid organs. Food poisoning by these organisms must be distinguished from typhoid and paratyphoid infections, the usual method being to test the agglutinating power of the patient's serum towards these various organisms.

The symptoms caused by *B. botulinus*, known as *botulism*, concern the nervous system, and consist of paralysis of accommodation, diplopia, ptosis, dysphagia, aphonia, and diminished salivary secretion. Death occurs with great suffering, since the patient retains full consciousness, while he cannot see, speak, or swallow, and his respiratory movements become gradually paralysed (56).

Treatment. In cases of gastro-enteritis the stomach should be washed out to prevent further infection ; and, except in cases of great collapse, a laxative should be given to clear out the intestines. Stimulants are often required, such as brandy, ether, and ammonia, and if the diarrhœa is a prominent symptom opium in small doses, 5 to 10 minims of the tincture. In cases of great collapse, normal saline solution should be injected into the subcutaneous tissue.

CÆLIAC DISEASE

This is the name given by Gee to an uncommon disease of children, which presents some similarity to sprue. The child, generally between the ages of one and five, passes abundant pale or almost colourless semi-fluid stools, like gruel or porridge, with a very offensive odour. These stools contain an excess of fat, and with the fatty acid there is a loss of calcium. The abdomen is full, but not tense ; there is flatulence, but no vomiting. Wasting of the buttocks is a characteristic feature. The child grows pale, thin, and apathetic ; irregular pyrexia may occur ; there is marked delay in the growth of the child, although the mental characters are normal : in fact, the disease is sometimes called *cœliac infantilism*.

The condition is occasionally encountered in adults and is called idiopathic steatorrhœa; usually the history can be traced back to childhood. The other characteristics are dilatation of the colon, tetany, osteomalacia, anaemia, skin lesions. The serum, phosphorus and calcium are low, hence the tetany, and there is increased output in the stools (51).

Owing to deficient absorption of fats symptoms of deficiency of vitamins A and D are constantly found, though rachitic manifestations may only be revealed during a period of growth. Another suggestion is that fat is excreted into the intestine, because the same oil when given by mouth does not appear in the fæces, indicating that absorption is satisfactory (Snapper). Other deficiency symptoms may occur from feeding difficulties. Severe anæmia is common. In the earlier stages this is usually microcytic; later it may be erythroblastic.

Treatment. Fats should be avoided, vitamins being provided in concentrated form. Many patients improve on a diet consisting largely of ripe bananas. Malted rusks, jellies, chicken, broth, rice boiled in water, potato, and revalenta prepared from lentils are usually well tolerated. In view of the very limited number of articles which can be given, changes should be as frequent as possible to prevent the establishment of strong dislikes, which so often add to the difficulties of feeding these patients. Liver extract and Marmite are necessary when the anæmia is megalocytic, and iron should be given in all cases in which anæmia is present. The prognosis is fairly good with suitable treatment.

PHLEGMONOUS ENTERITIS

In this form all the coats of the bowel are involved, including the serous coat or peritoneum. There is generally intense redness and vascularity, the mucous and submucous coats are thickened, softer, and more friable than natural, and the peritoneum is vascular, sticky, or covered with lymph. It may arise as a local inflammation or the result of a spread from adjacent parts or from intussusception or strangulated hernia.

Symptoms. These are often the result of the accompanying peritonitis, and consist of pain, vomiting, local tenderness, collapse, distension of the abdomen, and febrile reaction. The purely infective cases above mentioned have presented the symptoms of intestinal obstruction.

Treatment must be directed to the primary cause, and in its absence is practically the same as that of peritonitis.

COLITIS

Inflammation of the colon presents the same varieties as are seen in other mucous membranes, and may thus be catarrhal or ulcerative. Catarrhal colitis is often a part of a general entero-colitis, arises from the same causes, and has very similar symptoms—namely, pain, distension, tenderness, and frequent motions in which mucus, and even occasionally blood, are present. If the lesion is near the rectum, there may also be tenesmus. Catarrhal colitis may exist in an acute or chronic form, and the treatment is not materially different from that of enteritis. Both typhoid and tuberculous ulcers occur in the cæcum and ascending colon in association with similar lesions in the ileum; syphilitic ulcers occur in the rectum; colonic ulceration may also be caused by bacillary and amœbic dysentery, *Balantidium coli* infection and intestinal schistosomiasis (*Schistosoma mansoni* and *Schistosoma japonicum*). The so-called ulcerative colitis of asylums and jails which not infrequently occurs in epidemic form is really dysentery due to the Flexner Y group of organisms. The conditions are distinct from chronic ulcerative colitis described below.

MUCO-MEMBRANOUS COLITIS

(Mucous Colic, Mucous Colitis)

Muco-membranous colitis is characterised by the discharge *per rectum* of large pieces of membrane or *casts*. It occurs most frequently in middle-aged neurotic females, but is also not very infrequent in children. There is commonly habitual constipation with abdominal discomfort, and other symptoms of chronic dyspepsia. An attack of the disease is accompanied by severe griping pains, which result in the discharge of membranes.

The disease is associated with sudden spastic contractions of the colon with over-production of mucus. This becomes coagulated by a ferment, mucinase, since, owing to the contractions, it is retained for some time in contact with the mucous membrane before being eventually passed. The casts may be several inches or even feet in length, are quite thin and semi-transparent, looking like skins, and embedded in them are epithelial cells, eosinophil leucocytes, cholesterol, and ammonium magnesium phosphate. *Intestinal sand* may also be passed. There is usually some catarrhal colitis present. The narrowing of the lumen of the colon may be observed by taking a series of radiograms after the colon has been filled with an opaque meal. The sigmoidoscope should also be used, in case carcinoma of the pelvic colon is present, as this may give rise to the disease. According to Lockhart Mummery, the disease may be secondary to many conditions—pericolitis, kinking, visceroptosis, displacement of the uterus, etc.

In some of these cases injection, œdema, and ulceration of the mucous membrane have been seen with the sigmoidoscope.

Treatment. If possible the primary cause should be treated. Careful dieting so as to supply a food free from all mechanically irritating particles, fibres, etc., slow eating and careful mastication, and irrigation of the bowel with from 1 to 1½ pints of warm water or 10 ounces of olive oil, are useful means of treatment. Drastic purgatives should be avoided, because by irritation of the colon they will make the condition worse. Castor oil is the most suitable. Liquid paraffin may be used. Belladonna is useful for the pain. The abdomen should also be kept warm by means of an abdominal binder. Sometimes a diet consisting of fruit and vegetables, mostly uncooked, with coarse pods and skins—the antithesis of that described above—is useful, since it attacks the constipation which the patient suffers from. The mental symptoms should be attended to, and the patient's thoughts distracted from her malady. The disease does not endanger life, but it often lasts for years. Occasionally appendicostomy has been performed, and lavage carried out through the opening.

ULCERATIVE COLITIS

(Colitis gravis, Colitis ulcerosa gravis)

Chronic ulcerative colitis is a disease of unknown origin characterised by the frequent passage of faecal material associated with pus, mucus and blood. Pyrexia may or may not be present and acute and chronic forms of the disease may be encountered. Spontaneous remission is not infrequent.

Ætiology. Ulcerative colitis has a widespread distribution in Europe, America and elsewhere and affects both sexes, being most common in adult life. There may be no antecedent condition of ill-health, but certain cases have followed chronic septic disorders such as infected teeth, tonsils and sinuses, and by some this is held to support the view that a specific streptococcus (Bargen's diplo-streptococcus) is the causative organism. Others regard Flexner Y bacilli as the responsible ætiological agent, but the evidence that either of these specific organisms is responsible is far from satisfactory. It has also been suggested that following dietary deficiencies or some other cause which lowers colonic resist-

ance locally, the normal bacterial flora—especially streptococci—may take on pathogenic characteristics.

Pathology. The acute fulminating cases resemble bacillary dysentery; there is generalised intense inflammation of the mucosa with exudate, necrosis of membrane and widespread ulceration. The ordinary chronic case shows hyperæmia, œdema and miliary ulceration of the mucosa of the rectum which bleeds on instrumentation or swabbing; later, as the condition progresses, the colon becomes progressively involved with a granular bleeding inflamed surface; the walls of the bowel become thickened and fibrosed and narrowing of the lumen results. At autopsy in late cases the thick contracted bowel with large shaggy ulcers and strips of intervening mucosa, inflamed or polypoid, are very characteristic; in places the ulcers may be in process of healing with regenerating epithelium. Complete healing often leads to multiple polyposis.

Symptoms. In the acute fulminating type of case the onset is sudden with diarrhœa and colicky abdominal pain. The motions are dark brown, offensive and contain much mucus, blood and pus. The tongue is furred, the breath offensive and pyrexia perhaps associated with severe sweating develops. Abdominal distension and tenderness over the colon and some rigidity occur. Marked loss of weight and anæmia result and the patients may die without any remission of symptoms.

Chronic ulcerative colitis may follow the acute type, but much more frequently it begins as an apyrexial diarrhœa with the frequent passage of foul stools containing mucus, blood and pus. Rectal discomfort or tenesmus may develop and anæmia and loss of weight may ensue. Hypochlorhydria is not uncommon.

In 5 per cent. of cases the condition starts as a granular proctitis which gradually spreads up to the pelvic, ascending and transverse colons; ultimately the cæcum may be involved. Rarely segmental areas of the large bowel are affected without involvement of the rectum. Complications include hæmorrhage, perforation, stricture, polyposis of the bowel, carcinoma and arthritis; 20 per cent. of cases showing polyps develop malignancy later.

Diagnosis. The clinical history and appearance of the stools should arouse suspicion as to the nature of the malady, but diagnosis must be confirmed in every case by sigmoidoscopy and X-ray examination. Rectal examination may show an atonic sphincter and polyps may be palpated, while the gloved finger is covered in blood. Sigmoidoscopy reveals a uniformly inflamed, granular surface, bleeding readily on swabbing or instrumentation, and miliary or large-sized ulcers may be observed. The lumen of the rectum and colon is narrowed, its walls are inelastic and rigid so that distension with air causes pain. General anæsthesia is never necessary for sigmoidoscopy, and the patient may be examined in the knee-chest or dorsal positions. In a well developed case X-ray reveals a tubular, shortened bowel with complete loss of haustration, and if extensive ulceration be present, the colon presents a feathery and moth-eaten appearance. (Plate 29, A).

Prognosis. The fulminating cases may remain febrile throughout their course and may die in two to nine months from onset. The chronic cases may never develop fever, and in them remission of many months' or even years' duration may occur; in these circumstances all symptoms disappear and the bowel may even present a normal picture on sigmoidoscopy and X-ray. Later relapses generally occur; the course extends over many years and in some cases the general health is but little affected.

Treatment. Where fever is present rest in bed is essential. A nutritious, smooth, high calorie, high vitamin diet is desirable, and though it may be low in residue at first, fruits and puréed vegetables are included as soon as possible. A diet mainly of apples is sometimes successful. Eradication of septic foci is advisable, while treatment with autogenous streptococcal vaccine, Barger's anti-ulcerative colitic serum and anti-dysenteric serum (the latter daily in doses

of 10, 20, 40, 60, 80 and 100 c.c. intramuscularly or intravenously) are advocated by some ; but deaths have occurred from anaphylaxis. Colonic lavage with saline, sodium bicarbonate, protargol and albargin (1/500), pure potassium permanganate (1 grain to the pint), tannic acid (1 to 2 grains to the ounce) and eusol may prove useful. Duodenal irrigation every other day with warm sterile saline, sufficient in amount to wash the bowel free, is sometimes successful. A 5 per cent. suspension of bismuth subgallate in olive oil may be given daily. Iron therapy and blood transfusion may be advisable if the patient be anæmic, and acid. hydrochlor. dil. B.P. ($\frac{1}{2}$ to 1℥) given after food thrice daily. Operative intervention is dangerous owing to the risk of streptococcal peritonitis and should be reserved for intractable cases where medical treatment is of no avail. Appendicostomy, cæcostomy and ileostomy have their advocates ; they permit lavage with antiseptic solutions and the last operation rests the bowel completely.

APPENDICITIS

Ætiology. This disease is much more frequent in early life than in middle or old age, and in the male than in the female sex. The greater prevalence of the complaint in recent years, though generally admitted, is quite unexplained.

Pathology. Appendicitis is usually caused by infection by the *Bacillus coli communis*, which is a natural inhabitant of the bowel. Streptococci, staphylococci, *B. pyocyaneus*, and other pyogenic organisms, the tubercle bacillus, the typhoid bacillus, and actinomyces are sometimes concerned. The infection may be excited by a foreign body in the cavity of the appendix, obstructing the lumen. This may be a cherry stone, orange pip, seed, bristle, or similar substance. In many cases a concretion is found of the size of a pea, yellow or grey in colour, and consisting of faecal matter, mixed with mucus, lime salts, and numerous bacteria. This is now regarded as being formed subsequently to the catarrh of the appendix.

Morbid Anatomy. There is infiltration and thickening of the coats of the appendix, distension of its cavity with catarrhal products or pus, and, finally, ulceration and gangrene. In most conditions the trouble spreads to the peritoneal covering. The peritonitis may be localised and adhesive, matting the appendix to the adjacent bowel, and forming a more or less resistant mass in the right iliac region. An appendix abscess may be formed round the appendix, being shut off by adhesions from the general peritoneal cavity, while the appendix is usually found to be perforated or gangrenous. The appendix sometimes perforates or sloughs before adhesive peritonitis has occurred, and then a general peritonitis, of a very fatal kind, is rapidly determined. Occasionally a peritonitis, at first local, gradually extends with the formation of peritoneal abscesses in different parts of the abdomen, *e.g.* perinephric abscess, subphrenic abscess, or pelvic abscess. Exceptionally infective organisms are carried to the liver by the portal vein, and suppurative pylephlebitis and hepatic abscesses are the result.

If sloughing or suppuration does not take place, the apparent subsidence of the inflammation is by no means always the end of the disease ; the condition may relapse, and from six months to two or three years after the attack acute inflammation is again lighted up, and either terminates in one of the above processes or subsides again, perhaps to be active after yet another interval. In these intervals, as shown by operation in certain cases, the appendix presents thickening and infiltration of its walls, often with constriction in the middle, and dilatation at the distal end, with perhaps concretions in its cavity, and peritoneal adhesions externally ; or the cavity may be obliterated and the organ fibrous.

Symptoms. *Acute Attack.* The onset is often somewhat sudden. Spontaneously, or after a period of dyspepsia with or without some constipation or diarrhoea, the patient is taken with severe abdominal pain, at first diffused over the abdomen, but soon more pronounced in the right iliac fossa, with malaise,

nausea, vomiting, and some febrile reaction. The tongue is furred, the appetite fails, there is thirst, and the bowels are constipated. The abdomen may be somewhat distended, but is generally rigid and tender in the right iliac fossa. The rigidity may be absent if the appendix is situated in the pelvis. The tenderness is often definitely situated at a point about 3 inches from the right anterior superior spinous process, on a line drawn from this process to the umbilicus—*McBurney's point*. These symptoms may continue for a few days, the vomiting, pain, and tension may diminish under treatment, and the trouble may subside. The pain at the onset is not always diffused over the abdomen generally or situated over the appendical region: it may be epigastric or on the left side, it is frequently umbilical, and it may begin on the left side and go to the right side. There may be pain in the ilio-psoas muscle, elicited by hyper-extending the right hip while patient lies on his left side, or pain in the obturator internus muscle, elicited by rotating the right thigh outwards, with the knee bent, the latter when the appendix is in the true pelvis (*obturator sign*), occasionally there is pain in the penis.

When *perforation* with abscess formation takes place, and the appendix is situated above the brim of the true pelvis, the rigidity or resistance becomes more definitely localised and may form a definite tumour, bounded externally and below by the crest of the ileum and Poupart's ligament, and extending by a convex border half or two-thirds of the distance from Poupart's ligament to the umbilicus. It is often quite dull to percussion, and sometimes it has a modified tympanitic note, while the rest of the abdomen is supple and resonant. The temperature may rise to 103° or 104° F., the pulse to 100 or 120. The pain may be irregular or paroxysmal, and often shoots down the right leg. In favourable cases, if operation is delayed, the tumour may subside, gradually becoming less definite and smaller, so that it disappears in from ten to twenty days from the time it was discovered, while the fever and other unfavourable signs diminish. On the other hand, when the appendix is in the true pelvis perforation may lead to cessation of pain, while there is no abdominal rigidity, and the diagnosis may be missed, even though there is pelvic peritonitis. Apart from the "obturator sign" described above, a deep-seated abscess may be felt *per rectum* or *per vaginam*, or by its proximity (a) to the bladder may cause frequent micturition or (b) to the rectus may cause diarrhoea and tenesmus.

In cases of early *sloughing* of the appendix, the local indications may be entirely absent, or so slight that they are scarcely noticed by the patient, or of such short duration that the case is from the first, or quite early, one of general peritonitis (*see Peritonitis*).

Hyperalgesia, *i.e.* a feeling of soreness, or merely hyperæsthesia, *i.e.* increased tactile sensibility, may be valuable in diagnosis. They are elicited by drawing a pin over the skin held at a constant angle, or lightly picking up the skin between the finger and thumb. In acute appendicitis these signs are found in about 60 per cent. of cases and nearly always in the right iliac fossa, though there may be additional areas posteriorly and on the left side (58). Hyperalgesia is a referred pain, and the fact that it can be produced artificially by stretching the walls of a healthy viscus, and may last an hour or so after the stretching has ceased, shows that it has not necessarily anything to do with inflammation, but is the result of the secondary dilatation and stretching of the appendix walls or possibly a segment of ileum or cæcum.

In the relapses of appendicitis which have been already mentioned, the symptoms are precisely the same as occur in primary attacks; but the liability to general peritonitis is probably less, because adhesions will have formed around the lesion.

In subacute appendicitis deep pressure in the appendix region may cause a little pain, and thickening may be felt. Frequently it gives rise to troublesome symptoms, which are apt to be misleading, because they suggest disease

remote from the appendix. Thus the patient suffers from attacks of pain in the epigastric or umbilical region, sometimes even on the left side, or in the rectum, if the appendix is in the pelvis. In the last case there may be frequency of micturition, and in the other cases vomiting. The pain lasts from a few hours to one or two days. An important group of cases is that in which the symptoms are deceptively like those of gastric ulcer or less often of duodenal ulcer. In some cases pressure over the appendix causes a painful sensation in the epigastrium. The pain is aggravated by exercise or exertion. Attacks occur at intervals over some years, and in the intervals of the severe attacks the patient is in many cases not entirely free from pain. This simulation of gastric and duodenal disease is called *appendix dyspepsia*; and the symptoms are attributable to a dyspepsia produced reflexly from the appendix region.

Diagnosis. An apparently spontaneous acute general peritonitis in a boy or girl is nearly always the result of appendicitis; in older patients many lesions may be confounded with it. Nearly all the causes of the acute abdomen have been at different times mistaken for it (*see* p. 320). The past history, the seat of maximum pain and tenderness, and the local conditions as ascertained by examination externally and *per rectum*, must be carefully considered.

At a later stage, when a tumour has formed, this has to be distinguished from faecal accumulations, malignant growth of the cæcum, movable kidney, inflammation of the pelvic organs in women, and psoas abscess.

The diagnosis of appendix dyspepsia depends on some local signs being elicited in the appendix region, and on the absence of occult blood in the stools, (though it must be remembered that chronic appendicitis and peptic ulcer not uncommonly occur together), and on other negative evidence of peptic ulcer or cholecystitis. A valuable confirmatory test is *Bastedo's sign*. This is the occurrence of pain or tenderness in the right iliac fossa when the colon is inflated with air, slowly pumped in through a rectal tube. In the healthy person this produces some discomfort, but only pain in high degrees of distension, and then on both sides equally. When appendicitis is present, the inflation causes pain in the right iliac fossa; and the appendical region becomes tender to pressure, or, if previously tender, the sensation is aggravated. Sometimes also pressure in this situation will, after inflation, set up the very same pain in the epigastrium, which the patient has spontaneously suffered (Hurst). In a high percentage of cases the appendix can be seen by X-rays from six to eighteen hours after giving a meal of barium sulphate and buttermilk (Spriggs) or barium sulphate and water (Redding). More important than visualisation of the appendix itself is local tenderness, abnormal fixation of the cæcum and terminal ileum and delay in passage of food through the ileo-colic sphincter, *i.e.* deficiency of the gastro-ileal reflex, which is tested for by giving a meal four hours after a barium meal and examining the cæcum an hour later (35, 36).

Prognosis. In recent statistics from the London Hospital there was a 1.2 per cent. mortality of all cases of appendicitis operated on within the first twenty-four hours from the beginning of the attack. This had risen to 3.9 per cent. during the second day and to 8.7 per cent. during the third day. The earlier the operation, the better the prognosis.

Treatment. The facts that appendicitis may progress to the stages of gangrene and suppuration with so few symptoms, and that it is so difficult to ascertain without operation the extent of the danger, have led to the conviction that the removal of the appendix should be undertaken whenever a certain or highly probable diagnosis of appendicitis has been made; and this should be done at the earliest possible moment. If there is doubt about the diagnosis, or the symptoms are less urgent, it may be justifiable to wait; and then the patient should be put to bed, and fed only on milk, Benger's food, and similar articles of diet; hot boric lint or fomentations should be applied, and all aperients should be withheld, except a simple enema if the bowels have not recently acted.

Whether every case which has recovered under medical treatment should be operated on some months later to prevent recurrence is an open question ; but if a second attack occurs, certainly the opportunity should be taken to operate. The precaution should be taken to examine other parts of the abdomen, and particularly the gall bladder, for associated disease.

DIVERTICULOSIS

Multiple diverticula of the large intestine, which project out into the appendices epiploicæ through a series of small openings in the mucous membrane, may be found in any part of it, but the pelvic colon is affected in about three-quarters of the cases. The *prediverticular stage* is a local affection of the bowel and results from irritation. There is a little abdominal pain and local tenderness. The diagnosis is made by X-rays after an opaque meal (120 grains barium sulphate suspended in 500 c.c. Horlick's Malted Milk or buttermilk) or opaque enema (59). There is a ragged appearance of the outline of the colon (Fig. 49, B), while the segmentation between the normal haustra may be obliterated if that part is affected (A). The next stage is the formation of diverticula, flatulent distension being probably a predisposing cause (C). When there is faecal accumulation in the diverticulum it forms a stercolith, the barium only partly fills it, so that there is a cup-shaped shadow which moves as the haustrum contracts (D), and at times may be completely shut off from the colon by a strong contraction of the neck (E) (*see also* Plate 29, B, p. 370).

DIVERTICULITIS

Diverticulosis may continue for years without symptoms ; but *diverticulitis* may supervene at any time. The earliest radiological sign of this is shown at the neck of the diverticulum owing to infiltration at this point. The haustrum shows further excavation, with blunting of the re-entering angle (F). Most characteristic is the fact that the natural movement of the haustra shown by serial films is completely inhibited. In some cases the diverticula are shut off by the inflammatory thickening (I), or the necks may become so wide that the pouches become V-shaped (G, H) ; while an extreme obliterative stage from fibrous hyperplasia is shown at J. Other changes that may affect diverticula are (a) suppuration ; (b) perforation and peritonitis ; (c) fistulous communication with neighbouring organs ; (d) torsion of a diverticulum with strangulation ; (e) secondary development of carcinoma.

The symptoms of diverticulitis are those of a low form of inflammation in the large bowel, usually in the left lower abdomen, spreading to neighbouring structures. *Abdominal discomfort*, less often pain, not as a rule related to food, is situated about or below the umbilicus, but especially in the left iliac fossa, and is frequently intermittent. It may take the form of a dragging sensation and backache. General flatulence and a feeling of distension are usually mentioned and may be the only symptoms ; an advanced state of diverticulitis may, indeed, be present with but little complaint. *Constipation*, irregularity of the bowels, diarrhoea, or a sense of incomplete evacuation is frequent. In cases of implication of the bladder there may be *frequent micturition*, sometimes painful, after the bowels are opened ; or a painless micturition may be followed by pain. A sausage-shaped *tumour*, sometimes tender, but not always, can be felt in the left iliac fossa, except in the very obese. It may become acutely inflamed, with pyrexia and vomiting. Diverticulitis sometimes occurs at other parts of the colon. Hæmorrhage, per rectum, is not usual ; the inflammatory lesion lies, as a rule, without the mucous membrane.

Symptoms may arise from complications. When suppuration occurs there may be an acute inflammatory disturbance in the left iliac fossa resembling

the pelvic colon to be recognised (*see* p. 370). X-rays also may be used for diagnosis. An opaque enema, consisting of barium sulphate suspended in water by mucilage, is run into the rectum. If the funnel is held 2 feet above the anus, the mixture passes round to the cæcum, completely filling the colon, if the patient breathes deeply and at times alters his position. The colon must be emptied before the examination by giving castor oil thirty-six hours previously, supplemented by water enemas on the morning of the examination and the evening before. Any narrowing of the lumen or irregularity in its outline is suggestive of carcinoma (*see* Plate 30, A and B). An opaque meal traced downwards through the colon is of much less assistance in diagnosis.

In the later stages the patient may present the signs of acute intestinal obstruction, of chronic intestinal obstruction, or he may complain of an abdominal lump, which may be confounded with other lesions. Affecting the cæcum, it may resemble a chronic appendicitis, or enlarged glands; in the colon an enlarged kidney, a diverticulitis, an enlarged gall bladder, or an aneurysm if it overlies the aorta.

The treatment is surgical, and the prognosis good in the early stages. In inoperable cases deep X-ray therapy may be tried.

Polypoid growths, adeno-papillomas of the colon and rectum, occur in schistosomiasis.

Inflammatory Strictures of the Rectum. *Syphilis* rarely affects the alimentary canal between the pharynx and the rectum, but it sometimes causes stricture in this last situation. Gummas form in the submucous tissue and slowly lead to cicatricial contraction, owing to secondary inflammatory changes. Stricture may also result from gonorrhœa and more rarely from tubercle (48). They occur equally in both sexes, and little may be known of them till symptoms of stricture are observed, and the constriction is recognised by digital examination.

INTESTINAL OBSTRUCTION

The intestine may be obstructed in several ways: (1) foreign bodies; (2) intussusception or invagination; (3) changes in the intestinal walls, such as strictures caused by healed ulcers, or by malignant growths; (4) volvulus; (5) strangulation by bands or through apertures; (6) diminution of the calibre due to traction on the intestine, or to compression from outside in various ways.

Foreign Bodies. Among the foreign bodies found obstructing the bowels are fruit stones, pebbles, coins, bullets, pins, needles, hooks, and false teeth. Some large masses are formed of vegetable fibre, wool, or husks of oats, matted together. It is especially in lunatics that foreign bodies of these kinds are found. Occasionally a large gall stone is the cause of a fatal obstruction, or it passes *per anum* after more or less difficulty. Fæcal masses may accumulate in the same way as has been described under Constipation, and form a serious obstacle in the rectum or colon.

Intussusception. This presents special features which make it desirable to consider it separately (*see* p. 380).

Strictures. These occur both in the small and large intestines; they arise either from contraction of cicatrices of ulcers, or from new growths, and very occasionally from tuberculous infiltration in the intestinal walls. Simple tumours, such as *adenoma* and *fibroma*, are also occasionally the cause of intestinal obstruction.

Volvulus. By this term is meant the twisting of a loop of bowel upon itself, so that it becomes "strangulated," i.e. the pressure due to the twist is sufficient to interfere with venous return from the loop, but not with the arterial supply, so that congestion, hæmorrhage and gangrene supervene.

Strangulation by Bands and through Apertures. This class of case may be

called internal strangulated hernia ; a loop of intestine, commonly the ileum, slips through an aperture, such as the foramen of Winslow, and is strangulated by the margin of the aperture grasping its neck. But more frequently the constricting ring is formed by a band of adhesion stretching from one part of the abdomen to another, under which the loop of gut passes. A frequent cause of this form of obstruction is the congenital abnormality known as *Meckel's diverticulum*. This forms a finger-like projection from the unattached side of the ileum, from 2 to 4 inches in length, and $\frac{1}{2}$ to $\frac{3}{4}$ inch in diameter. It is a remnant of the omphalo-mesenteric duct, by which the primitive alimentary canal communicates with the yolk sac. It arises from the ileum, at a point 18 to 24 inches from the cæcum, and its blind termination is generally free ; but it may be attached by a fibrous band to the anterior abdominal wall at the umbilicus, or to the mesentery, or to the peritoneal surface at some other point. A ring is thus formed, through which a loop of gut may slip, and then become strangulated.

Compression and Traction. This class includes acute kinking due to traction by an isolated band ; adhesions compressing the gut ; and matting together of several coils.

Pathology. In a fatal case of acute obstruction of the intestine, the bowel above the seat of obstruction is found enormously distended, while that below is collapsed and empty. The distension begins immediately above the constriction, and affects the bowel for a greater or less distance, according to the severity or duration of the obstruction. Thus in obstruction at the sigmoid the whole colon and much of the small intestine are affected ; in obstruction of the ileum the small intestine is distended and the colon is collapsed. In the upper distended portion is a quantity of faecal matter, light brown or yellowish brown in colour and of uniform thick liquid consistence ; and this is the same whether the obstruction is in the small or large intestine. In chronic cases the distended bowel may become gradually hypertrophied from its efforts to overcome the obstruction ; eventually the bowel may yield in the distended portion above, and so-called *stercoral ulcers* may be formed, some of which may perforate. In acute strangulation sloughing may occur at the seat of constriction, from direct interference with the circulation.

Continued acute intestinal obstruction is a fatal disease, and the higher the place of obstruction the quicker is the onset of death. Biochemical changes, somewhat similar to those of an allergic attack, are present (*see p. 138*) ; *i.e.* in the blood there is a rise of non-protein nitrogen and bicarbonate, with alkalæmia, and a fall in the chloride, which disappears into the tissues (61), and the same explanation of a sudden protein catabolism or protein shock may well hold good. It has also been suggested that there is an abnormal proliferation of *B. welchii* with absorption of the toxin from the small intestine ; this may initiate the protein catabolism. Favourable results from injecting the antitoxin have been reported (62). Another suggestion is that the presence of bile in the intestine is a necessity, and this is hindered. Favourable results from rectal injection of bile have also been reported (63).

Symptoms of Acute Obstruction. In a case of strangulation by a band the patient is seized with intense pain in the abdomen, generally in the neighbourhood of the umbilicus ; he may be walking about, or having a meal, or he may be awakened from sleep. The patient then vomits. Neither motion nor flatus is passed *per anum* ; and the vomiting, at first gastric, then bilious, becomes ultimately stercoraceous. The effect upon the patient is very grave. Collapse soon sets in ; the face is drawn, the eyes are dark and sunken, the pulse small and quick, the temperature normal or subnormal. The tongue is dry, and there is constant thirst. Abdominal distension is usually a later sign and varies with the position of the obstruction ; if this is in the upper part of the small intestine, the abdomen may be flat, or distended only at the upper part, above the umbilicus ; if the lower part of the ileum or large intestine is strangulated, distension

occurs sooner and the abdomen is uniformly enlarged. Tenderness is usually delayed till distension takes place. If the condition is unrelieved, death supervenes, either from exhaustion or from acute peritonitis, of which a general diffused tenderness may be the chief indication. The duration of the case is from four to six days.

When the intestine is obstructed, but not strangulated, the onset is more insidious; the pain is intermittent and less severe; fæculent vomiting and distension are delayed, and the abdominal wall remains flaccid.

The symptoms due to obstruction by a gall stone are often characteristic. At first they are acute, due to ulceration into the duodenum, and afterwards to obstruction of the duodenum by the stone; there is passage or vomiting of blood. Then they disappear as the gall stone passes along the small intestine, to reappear acutely in a day or so if the stone is held up at the ileo-cæcal valve.

Symptoms of Chronic Obstruction. In chronic obstruction such as is due to malignant disease of the pelvic colon or of the descending colon, the symptoms are at first only indicative of a moderate interference with the passage of fæces; there are some local pain and occasional vomiting, not particularly related to the ingestion of food. Constipation occurs irregularly, but it can be overcome by aperients. From time to time the constipation is very troublesome, vomiting is more frequent, yet not stercoraceous, the abdomen becomes greatly distended, and the hypertrophied coils become visible in peristaltic movements on the surface of the abdomen. With the peristaltic movement can be heard gurgling sounds, or borborygmi.

From time to time some fluid motions may be passed, and there may be several large evacuations of liquid fæces, by which the abdomen is rapidly reduced to its normal capacity, and all the symptoms are relieved. This sequence of events may recur more than once, but in some such attack the obstruction becomes complete, and acute symptoms supervene as described above.

Position of the Stricture. The differences to be noted between strictures of the small intestine and those of the large are that in the former vomiting occurs earlier, and is more determined by the ingestion of food; in the latter, as already described, distension is greater, and the proximity of the stricture or growth to the anus may lead to alterations in the shape of the motions, which may be ribbon-shaped; and tenesmus is frequently present. When the distension mainly affects the colon, a number of enlarged vertical coils may be seen, due to the distended ascending and descending colon and to the transverse colon, which bends downwards in the middle and forms two others. When the small intestine is chiefly distended, and the colon is collapsed, the distended coils lie transversely across the abdomen, forming the so-called "ladder pattern."

Diagnosis of Obstruction. Before distension takes place acute intestinal obstruction is distinguished from the various acute abdominal catastrophes such as *perforation of peptic ulcer*, *appendicitis*, *acute hæmorrhagic pancreatitis*, and *cholecystitis* and the *colics* (see p. 363), by the absence of rigidity and by the more frequent vomiting which tends to become fæculent. When distension is present intestinal obstruction must be distinguished from the later stage of acute peritonitis due to any cause. The presence of acute stasis may be determined by administering two turpentine enemas at a few hours' interval; the first empties the lower bowel; the second proves the constipation. The rectum should also be examined by the finger; it is often empty and dilated, or "ballooned," in cases of obstruction.

The other conditions that must be differentiated are *mesenteric embolism* and *thrombosis* and *Henoch's purpura*, which all produce similar symptoms; but some blood will usually be obtained by an enema. Acute obstruction may be simulated by some conditions of nervous or toxic origin in which mechanical or inflammatory lesions have no part. One is the *gastric crises* of *tabes dorsalis*, in which pain and vomiting occur; but the abdomen is retracted, and the vomited

fluid, though abundant, is dirty green and watery, but not fæcal. A history of similar attacks in the same patient, and the absence of knee jerks and of the pupil light reflex, would speak for tabes. Another condition is the acute pain of commencing *diabetic coma*, which has more than once nearly led to operation; the patient is generally beginning to be drowsy, and sugar and aceto-acetic acid are found in the urine, if looked for. *Uræmia* may be difficult to diagnose, especially as similar biochemical changes occur; but the vomiting will not be fæculent. The possibility of obstruction from an extra-abdominal hernia, whether inguinal, femoral, or obturator, should not be forgotten.

Treatment. When the diagnosis of acute intestinal obstruction is established the operation of *laparotomy* or opening the abdomen should be performed without delay; and the cause should be ascertained and an attempt made to remove it, or if necessary the bowel should be simply opened at the most distended part above the obstruction, and a fæcal fistula established. Saline infusions and rectal injections of 6 per cent. dextrose may be given with great advantage. Treatment with anti-Welch serum (80 c.c. intramuscularly repeated as required daily) and with rectal injections of bile have already been mentioned. It is rarely wise to give opium or morphia for the relief of pain: it has the serious disadvantage that, while easing the pain and checking sickness, it removes two important symptoms, and may lull to a false security while the fatal mischief is progressing. Locally relief may be furthered by the application of turpentine stupes; or of flannels wrung out of hot water, and sprinkled with tincture of belladonna, or opium; or of hot linseed-meal poultices.

In *chronic* obstruction, which is chiefly the result of strictures and growths, whether in the small or large intestine, the diet must be carefully selected, with the object of ensuring regular digestion and the easy passage of the intestinal contents through the constriction. Enemas, and occasionally laxatives, may be used to maintain a periodical evacuation. If an obstinate constipation ensues, and especially if great distension and sickness occur, the treatment should be similar to that of an acute obstruction. Opium may be given, with or without belladonna, while food must be given in only small quantities, or *per rectum*, when relief may be shortly obtained. Eventually, if life is to be prolonged, an operation will become necessary.

For fæcal accumulations large and frequently repeated enemas generally suffice, but the case requires to be long under treatment by careful diet, exercise, electricity or massage, to restore the bowel to its former power.

INTUSSUSCEPTION

If one segment, say a few inches, of the intestine slips into the portion immediately adjacent, it forms an *intussusception* or *invagination*. It will be at once seen that this must present from without inwards to the centre of the bowel three layers of bowel wall, of which the innermost may be called the *entering* layer; the outermost, the *receiving* layer or *sheath*; and the portion joining these two, the *middle* layer. It is clear that a portion of bowel might slip into a segment above, forming an *ascending* intussusception, or into the bowel below, forming a *descending* intussusception. It is with the latter that we practically always have to do.

Intussusceptions occur at any part of the bowel, and have received names accordingly; thus those of the small intestine are called *enteric*, those of the large intestine *colic* or *rectal*. But at the point of junction with the ileum and the colon two varieties occur—(1) the *ileo-cæcal*, in which the ileum and cæcum pass into the ascending colon, the ileo-cæcal valve forming the most advanced point, the ileum the entering layer, and the cæcum the most advanced part of the middle layer; (2) the *ileo-colic*, in which the lowest part of the ileum is inverted through the ileo-cæcal valve—that is, an enteric intussusception continued into the colon

Of the different forms the ileo-colic is the rarest, and the ileo-cæcal is the most common, forming nearly half of all cases.

Very important changes, dependent on the anatomical relations of the intestines, ensue upon an intussusception. The intussusception, if at all extensive, forms a thick cylindrical swelling, partly from containing three layers of bowel all round instead of one, partly on account of the congestion and œdema to be presently explained. From the mesenteric connections of the bowel this cylinder has a curved shape, since the vessels which supply the inner and middle layers are of the same length as those supplying the receiving layer, and yet have not only to reach the border of the intussusception, but to go into its interior between the inner and middle layers, so that they drag upon the upper end of that part of the bowel. As the intussusception increases it moves farther along the gut, and the internal cylinder of an ileo-cæcal intussusception may even reach the rectum and project from the anus. At the same time the tumour becomes larger. The disposition of the vessels just described leads to their compression and strangulation, and consequently to congestion and œdema of the walls of the intussusception, and even to hæmorrhage from the mucous surface, and the discharge of blood *per rectum*, an occurrence of the greatest value in diagnosis. If the case is not quickly fatal, inflammatory changes ensue in the layers of the bowel, binding them together, and interfering both with the further progress and with the reduction of the intussusception; and, lastly, from the strangulation of the blood supply to the entering and middle layers, these may become gangrenous, slough off, and be discharged *per rectum*. If this has been preceded by the secure adhesive union of the entering layer to the angle between the outer and middle layers, the canal of the bowel is practically restored, and an actual cure may be the result, though this is very rare; if the union is imperfect, the detachment of the inner cylinder is followed by a fatal extravasation.

Ætiology. Enteritis is the commonest predisposing cause of intussusception. Sometimes intussusception has arisen after direct injuries. Sometimes intestinal polypi and carcinomatous tumours are responsible, and in Henoch's purpura it appears to be caused by hæmorrhage into the intestinal wall. It may happen at all ages, but is much more frequent in children. Little that is definite can be said as to the immediate mechanism of intussusception, except that it is due to an irregular peristaltic action.

Symptoms. The onset of an acute intussusception is not unlike that of strangulation by bands—that is, the patient is rather suddenly seized with pain, which is more or less constant, though aggravated from time to time, and griping in character. In the baby, the onset is indicated by screaming. Nausea and vomiting also occur, but constipation is not generally present at first; on the contrary, the bowels are usually moved, and either thin fæces, or (what is especially characteristic of intussusception) blood with or without mucus, is passed. Indeed, blood is passed *per rectum* in four-fifths of the acute cases; and often a certain amount of tenesmus is present. The abdomen is not always much swollen, but an examination reveals generally another characteristic feature—the presence of the *tumour* which results from the intussusception. Its position is, of course, related to the site of the lesion; in the more ordinary ileo-cæcal form it is at first situate in the right flank, but as the intussusception increases it is felt in the umbilical region, and is generally oval, cylindrical, or sausage-shaped, lying transversely across the abdomen above the umbilicus. Subsequently it passes into the left flank and left iliac fossa, and ultimately can be felt by the finger in the rectum, or actually projects from the anus. Sometimes there is complete constipation, with much distension, and fæculent vomiting; at others collapse sets in rapidly, and death takes place in twenty-four hours, or from two to five or six days. Death is especially rapid in quite young infants.

But the symptoms are not always so acute; indeed, an intussusception may exist for weeks or even months. In these more chronic cases the extent of bowel

involved is generally less, and the canal is not completely obstructed. The bowels may thus be opened, though blood is passed at the same time in about half the cases. The patient suffers from paroxysmal griping pains, not necessarily of great severity. The abdomen is flaccid, and the tumour presents an important characteristic, namely, a varying consistence, so that it hardens simultaneously with the griping pains, but soon becomes soft, and even imperceptible when they subside.

The terminations of the subacute and the chronic cases are various ; they may ultimately lead to death by exhaustion, or to complete obstruction with vomiting, constipation, abdominal distension, and visible coils ; or they may set up a local peritonitis, followed by the formation of abscess, or by a more general peritonitis ; or the intussuscepted portion may separate by sloughing, and so the intestinal canal may be re-established.

Diagnosis. Spasmodic pain, vomiting, the passage of blood *per rectum* and the presence of an oval or elongated tumour which varies in consistence from moment to moment, and lies in the course of the colon, or occupies the rectum, are the chief features of intussusception ; but the tumour cannot always be felt, especially in infants with a much-distended abdomen, unless an anæsthetic is given. *Enteritis* and *dysenteric diarrhœa* in children may resemble it, and a piece of contracted gut sometimes forms a tumour ; the blood is more often mixed with mucus. In Henoch's purpura there may be lesions elsewhere and also multiple arthritis. X-ray examination after a barium enema may be used.

Treatment. An *acute* intussusception should, as soon as possible, be met by an effort at reduction, and though cases have been successfully treated by injection of fluids into the rectum and colon, it is safer and more certain for the surgeon to perform laparotomy and reduce the intussusception by careful traction. In the longer-standing cases adhesions may render reduction impossible ; and then a portion or the whole of the mass must be resected.

In *chronic* forms when the nature of the lesion is recognised, operation should also be performed.

HIRSCHSPRUNG'S DISEASE

(*Megacolon*)

This is a rare disease, of which the feature is chronic dilatation and hypertrophy of the colon. In many cases the symptoms begin in the first few weeks of life, in others in early childhood, and in others later. There is constipation, obstinate and repeated, the bowels remaining unopened for two or three weeks at a time. The abdomen is distended enormously, so that the pressure on the chest may itself be a danger. The distended coils of the colon may be seen through the abdominal walls. Peristaltic movements are visible in the coils. The child is emaciated, and in the older patients defective nutrition and sallow skin are observed. The disease does not run a rapidly fatal course ; but death from intercurrent disease and toxæmia is to be feared. After death the colon is found to be dilated to two or three times its normal diameter, and often much elongated ; and in long-standing cases the muscular fibres, especially the circular layer, are much hypertrophied. There are two types of cases, about equally common, according as the dilatation begins immediately above the anus, or above the pelvi-rectal flexure. The most reasonable view of the pathology is to correlate the disease with chronic dilatation of the œsophagus and to regard it as secondary to obstruction (achalasia) of the anus or pelvi-rectal flexure (64).

Diagnosis. Megacolon is not so very uncommon ; large amounts of gas are seen in the intestines by X-rays, forcing up the left diaphragm and rising above the liver. A sigmoidoscope is introduced with ease and a dilated colon is seen ; this is also shown by barium enema.

Treatment. Attempts must be made to keep the colon free. Purgative

drugs are of little value. In the anal variety the colon may be readily washed out daily through a rectal tube; the latter may be left in at night. In the pelvi-rectal variety the treatment is not so easy; but enemas of oil or glycerine may do good.—Pituitrin—1 c.c. injected—electricity and abdominal massage may also help. The anal sphincter may be dilated. An operation may be necessary, either a colostomy, or ileocolostomy, or complete resection of the dilated part of the colon.

EXAMINATION OF THE LIVER

The liver occupies the right hypochondriac region, under the ribs, and stretches across the upper part of the epigastrium. Normally it can scarcely be felt even in the latter situation, and there only when the abdominal wall is very thin. Percussion gives dulness (*hepatic dulness*) in the mammary line, from the upper border of the sixth rib to the costal margin. In the axillary line the hepatic dulness begins at the eighth rib, and in the line of the scapular angle at the tenth or eleventh rib. When the organ is enlarged it projects below the costal margin, its lower margin extending across the abdomen from the right flank to the left costal margin. The dulness extends to a corresponding degree down into the abdomen; but from the presence of the intestines behind it the dulness is not so complete near the free edge as it is higher up. The liver only encroaches on the chest when the enlargement is (1) localised rather than general, such as that due to carcinoma, hydatid, or abscess; or (2) when the liver is itself pushed up by something below.

Apparent enlargement of the liver arises from tight-lacing, and from tumours or pleuritic fluid in the chest. The former elongates the organ vertically; in the latter the whole liver is displaced. Displacement of the liver downwards, or ptosis, occurs also as a part of *Glénard's disease* (see p. 339). A distended gall-bladder may be felt as a globular prominence at the lower border of the hepatic dulness, in the mammary line.

The hepatic artery supplies about 20 to 30 per cent. of the blood flowing to the liver and the portal vein the remainder; the liver of a dog receives each minute about four-fifths of its weight in blood. The true anatomical division of the liver is into two equal lobes, indicated by a line drawn from the fundus of the gall-bladder to the groove for the inferior vena cava and not by the falciform ligament. The portal vein contains two more or less separate blood currents side by side; the "stream line" from the mesenteric area goes to the right lobe and that from the spleen to the left (65). The spleen and liver can be made opaque to X-rays by injecting intravenously a preparation of thorium (thorotrast), which is taken up by the reticulo-endothelial system (66).

LIVER FUNCTION AND FUNCTIONAL TESTS

Accurate knowledge of the function of the liver dates from the operation devised by Mann for removing the livers from dogs (67). After the operation the animal appears normal for three hours or more, but severe symptoms of muscular weakness come on rather suddenly, and later there are twitchings and convulsions. These are due to hypoglycæmia and can be arrested by giving sugar, so that the animal again becomes normal for a time; but then more severe symptoms appear in spite of treatment and the animal dies in coma. Hypoglycæmia results because the body burns up sugar continuously, and the one source of supply, the liver, is missing. Other biochemical changes are a fall in blood urea and in the ammonia and urea of the urine, while there is a rise in the amino-acids; the reason is that in the liver deamination with the formation of urea is naturally brought about, and some of this urea is converted into ammonia by the kidneys. There is a rise in blood uric acid, because the liver

naturally destroys it, though there is some doubt about this in man. There is jaundice, because bilirubin is formed by the reticulo-endothelial cells of the spleen and marrow (also by the Kupffer cells of the liver) by splitting off the iron-containing part from blood pigment. The liver cells collect this bile pigment, secreting it into the bile canaliculi and then into the bile ducts (68). All these changes have been observed from time to time in severe liver disease, *i.e.* acute necrosis and carcinoma. In addition, the liver has detoxicating properties, and in disease the blood fibrinogen, which is produced by the liver (69), may be diminished, leading to hæmorrhage, and the serum calcium also falls. There may be urobilinuria, because normally bilirubin is converted into urobilin in the alimentary canal, some of which is excreted as the stercobilin of the fæces, but the rest is absorbed by the alimentary canal and returns to the liver to be reconverted into bile pigment; when liver function is impaired, it escapes into the general circulation and is excreted by the kidney as urobilinogen.

The normal liver has great powers of regeneration, so that if 70 per cent. is removed the normal amount will be found in a few weeks. Quite a small amount of liver is sufficient for most of its activities, so that marked changes, like hypoglycæmia, are only found in the most severe stages of the disease, and in the milder forms the so-called functional tests, of which a very large number have been described, are apt to lead to rather uncertain results. The more important ones are described below.

Lævulose Test. This test depends on the fact that when lævulose is absorbed from the alimentary canal and reaches the portal circulation, it is almost entirely taken up by the liver, and so does not reach the systemic circulation. If the liver is diseased, the lævulose is not retained. It passes through into the systemic circulation and causes a rise in blood sugar (*see p.* 462). In performing the test, a dose of 50 grams of lævulose is taken by the mouth. The blood sugar is estimated first beforehand, and half an hour, one hour, and two hours later. Normally there may be a very slight rise, which is less than 0.01 per cent. Thus if the blood sugar is 0.10 per cent. it will not be higher than 0.11 per cent. after an hour. If the liver function is deranged, as may occur in catarrhal jaundice, or in arsenobenzol poisoning, the blood sugar may rise to 0.15 per cent. in half an hour and 0.19 per cent. at the end of an hour, and it then slowly returns to normal (70). Simultaneously with the rise in blood sugar the lævulose often appears in the urine, as the kidney very readily excretes it. This test should be compared with that for mild diabetes mellitus (*see p.* 464). **Galactose** (40 gram. in 400 c.c. water) is also employed as a test like lævulose, since normally there is no rise of blood sugar, or at most 0.03 per cent., though with children higher rises up to 0.1 have been found (71). The urine normally contains less than 1 gram. of galactose during the succeeding three hours (72), or 2 grams in six hours.

Gross inefficiency of hepatic function may be shown by the occurrence of jaundice or ascites, which will now be described. In this connection certain special tests are available, *viz.* Van den Bergh's tests, Hay's test for bile salts, and the examination of the urine for urobilin (*see pp.* 386, 509).

JAUNDICE

The term *jaundice* (from *jaune*, yellow), or *icterus*, denotes the circulation in the blood of constituents of bile. In the past the term has been used solely for the yellow staining of the skin and mucous membranes by bile pigment, but it is now used in a wider sense and includes those cases where bile salts appear in the blood without bile pigment—one form of *dissociated icterus*, and cases where the bile pigment is present in such small quantity that no colour is produced (*latent icterus*).

Symptoms. Owing to the colour of bile pigment the skin has a more or less deep yellow tinge, the conjunctivæ are yellow, and the visible mucous mem-

branes have their natural colour obviously modified by the yellow tint. In long-standing cases the colour of the skin becomes deeper, and finally of a greenish or olive-brown tint. This, formerly distinguished by the name of *green* or *black jaundice*, is due to the gradual conversion in chronic cases of bilirubin, the yellow pigment of the bile, into biliverdin by oxidation in the skin. The yellow colour must be distinguished from other changes of colour in disease, such as the lemon yellow tinge of cases of pernicious anæmia, the sallow tint of malarial cachexia, the brown colour of Addison's disease, and the yellow colour due to the pigment *carrotin*, which appears in the skin after eating large amounts of green vegetables and carrots. The colour can be generally well recognised in the conjunctiva, but in some people small masses of subconjunctival fat give a tint which is not very unlike it.

The colour of the *urine* is at the same time altered, from the presence of the biliary pigment. In small quantity this gives it a bright saffron colour, which is best seen in any froth which may form on the surface; if there is more the urine becomes brownish yellow, or yellowish brown, or even dark brown like porter. If linen or paper is dipped in the urine, it is stained bright yellow; but the presence of bile pigment can be more certainly proved by the application of chemical tests which will be mentioned presently. Of the other secretions of the body the sweat is sometimes tinged yellow. The milk of nursing women, tears, and saliva are rarely stained. The cerebro-spinal fluid is not usually stained. At the commencement and at the end of an attack of jaundice the urine often contains urobilin, a derivative of bile pigment, but none of the bile pigment itself, and there is a group of cases in which bile pigment is absent from the urine (*see Acholuric Jaundice*).

In most cases of jaundice the *fecæ* are altered in colour, becoming whitish or clay-coloured; this is due to the presence of an excess of fat and to absence of urobilin in those cases of jaundice where the bile is unable to find its way into the duodenum. It has recently been shown that the intestinal contents are slightly acid and that fat is absorbed in the form of a compound of free fatty acid with bile acids. The presence of bile, also, probably prevents putrefaction and stimulates the muscular fibres of the intestinal wall. Accordingly constipation is frequent, though by no means invariable. When diarrhœa occurs, it has been attributed to the irritation of the putrescent fecæ.

Other symptoms are often present in jaundice, which are due to the circulation in the blood of bile salts. These are: (1) *bradycardia*; the *pulse* becomes slowed to fifty or forty per minute; (2) *itching*; it may be so intense that sleep is rendered impossible, and blood crusts, papules, or wheals of urticaria are produced by the incessant scratching.

Some patients have a bitter taste in the mouth, and digestive disturbances are frequent. Hæmorrhages take place under the skin or from the mucous surfaces, and the bleeding from wounds is not readily checked; the coagulation time of the blood is prolonged. In some cases, serious cerebral symptoms arise, such as delirium, convulsions, and coma; but these are probably always due to the presence in the blood of other poisons than those contained in the bile. Yellow vision (*xanthopsia*) is sometimes observed. A disease of the skin named *xanthelasma* or *xanthoma* occurs in some cases of long-standing chronic jaundice (*see Diseases of the Skin*).

Clinical Tests for Jaundice. *Van den Bergh's Test for Bile Pigment in Serum.* Besides indicating the presence of bile pigment in serum, this test differentiates between the pigment retained in the blood from obstruction of the bile passages and that due to hæmolysis. Ehrlich's diazo reagent is used. This consists of (a) sulphanilic acid 1 gramme, conc. HCl 15 c.c., distilled water 1,000 c.c.; and (b) sodium nitrite 0.5 gramme, distilled water 100 c.c. The two are mixed just before use in the proportion of 25 c.c. of (a) to 0.75 c.c. of (b). *Direct Reaction.*—One cubic centimetre of serum obtained from blood, allowed to clot on standing,

and 1 c.c. of the reagent are mixed. A bluish-violet colour reaction begins immediately, and is at its maximum in ten to thirty seconds. This indicates obstructive hepatic jaundice. If there is no direct reaction, a delayed reaction may occur, beginning after one minute. This is due to hæmolytic or toxic and infective jaundice. A biphasic reaction, which begins at once, but only slowly develops, indicates the presence of a mixed type of jaundice. *Indirect Reaction.*—If no direct reaction is given, 2 c.c. of 96 per cent. alcohol are added to 1 c.c. serum and centrifugalised. To 1 c.c. of the clear liquid 0.5 c.c. of alcohol and 0.25 c.c. of the reagent are added. A violet-red colour, which is of maximal intensity almost at once, is obtained, and this indicates hæmolytic or toxic and infective jaundice. The tests may be carried out quantitatively (73); the normal range is 0.2–0.5 unit, a unit being 1 part bilirubin in 200,000.

Tests for Bile Pigment in the Urine. The essential feature of these tests is the production of a green colour by the oxidation of yellow bilirubin into green biliverdin; in some processes other tints are temporarily developed. *Gmelin's test* may be carried out as follows: A few drops of urine are placed upon a white plate, and a little strong nitric acid is dropped close by, and then the two fluids are gently run into one another. At the line of contact the colour of the urine changes, becoming green, blue, violet, red, and lastly yellow or brown. *Ryffel* has devised a modification of this test capable of detecting very small quantities of bile pigment. The urine is saturated with ammonium chloride and made alkaline with ammonia. Ammonium urate is thus precipitated and carries down any bile pigment with it. The urate is filtered off, and nitric acid is added to the residue on the filter paper. A green colour indicates bile pigment.

Hay's Test for Bile Salts in Urine is carried out by sprinkling powdered sulphur on to the surface of fresh urine in a small conical flask illuminated from the side. If bile salts are present the surface tension is lowered and the sulphur sinks, and the test is positive if there is definite sinking in five minutes (71). This test, which has been much discredited in the past, is now regarded as reliable; but the test is also given if large amounts of sandal-wood oil, copaiba, cubebs and turpentine have been taken by mouth. A test for the presence of bile salts in the intestine, depending on the fact that they facilitate absorption of fat, has also been described (74).

Pathology of Jaundice. Bilirubin exists in two forms: (1) as an alkaline salt which is excreted into the bile passages. This gives Van den Bergh's direct reaction; (2) as a free acid circulating in the blood which gives Van den Bergh's indirect reaction (77). That the liver is not necessary for the production of bilirubin has already been pointed out, and it is also shown by the fact that this pigment is formed locally from old blood clots anywhere in the body. If something goes wrong with the formation by the reticulo-endothelial system, which forms bilirubin, or blood destruction in the body is excessive so that the manufacture of bilirubin by these cells is greatly increased, pigment will not all be taken up by the liver and excreted as bile, but will gain entrance to the circulation. This result may also occur if the liver cells are damaged. There are thus three types of jaundice:

1. *Hæmolytic Jaundice*, a group which includes the blood disease of this name, since owing to excessive blood destruction bilirubin is present in the serum. The group includes the jaundice that may result from paroxysmal hæmoglobinuria, transfusion with incompatible blood, phenyl hydrazine poisoning, hæmolytic septicæmias, lobar pneumonia, malaria and icterus neonatorum. Pernicious anæmia is sometimes included, though the bilirubin accumulates probably because the formation of hæmoglobin is defective.

2. *Jaundice due to Primary Liver Damage.* The causes are (a) congestion from heart failure; (b) primary disease of the liver, such as most cases of catarrhal jaundice, acute necrosis (yellow atrophy), Hanot's cirrhosis, multilobular cirrhosis in the later stages, and certain conditions classified previously under the

heading *toxic and infective hepatic jaundice* ; the agents are—(i) *chemical poisons*, such as tetrachlorethane (*i.e.* dope for aeroplanes), T.N.T., chloroform, phosphorus, toluylene-diamine, nitrobenzene, arsenobenzol derivatives, arseniuretted hydrogen, mushrooms, snake venom, etc. ; (ii) *bacterial poisons*, such as occur in relapsing fever, malaria, the enteric group, typhus, pneumonia, influenza, syphilis, yellow fever, septicæmia, leptospiral jaundice, etc.

3. *Obstructive Hepatic Jaundice.* In this group there is some obvious obstruction of the bile ducts : (1) gall stones and inspissated bile, very rarely hydatids, liver flukes, and foreign bodies from the intestinal canal, including *Ascaris lumbricoides* ; (2) stricture or obliteration of the duct from congenital defect or atresia, or from former ulceration of the duodenum or of the bile duct itself : catarrhal or inflammatory swelling or carcinoma of the wall of the bile duct : spasm of the duct ; (3) compression from the outside by glands in the portal fissure : by tumours of the head of the pancreas, stomach, colon, kidneys, omentum, ovaries, or uterus : by abscess or hydatid of the liver : by an abdominal aneurysm, accumulated fæces, or pregnant uterus. In many cases of obstructive hepatic jaundice the bile distends the gall bladder and the bile ducts, and then passes into the lymphatics and blood vessels, circulates in the latter, and gives the characteristic tinge to the skin and other parts. An interesting fact in the secretion of the bile makes it likely that a complete obstruction is not necessary—that is, that the bile is secreted under very low pressure, such that in guinea-pigs a pressure of 20 cm. of water will force the secreted bile back into the circulation. Where there is a complete obstruction, as from a gall stone in the common duct, or a tumour pressing upon it, the bile is unable to reach the intestines, and the fæces, as already stated, are white or clay-coloured. When the obstruction is relieved the symptoms disappear.

While the first and third of these types of jaundice are clearly differentiated, since they give respectively the indirect and direct Van den Bergh reactions, members of the second group commonly give a biphasic reaction. In the past the jaundice in these cases has been looked upon as due to a cholangitis affecting the smaller bile ducts and therefore obstructive ; but this view has been attacked by Brulé, who points out that sometimes the bile salts alone are retained in the circulation and at other times the bile pigments alone—these are the two types of *dissociated jaundice*—so that the liver cells themselves must be implicated (74). He regards the jaundice due to cirrhosis, concussion or congestion in heart disease as belonging to the same group. It has been found that in obstructive jaundice the blood phosphatase is increased, and this may be helpful in diagnosis (75).

Latent Jaundice means that there is bilirubin in the blood, but not enough to produce a typical yellow colour or to cause the kidney to excrete bilirubin. In such cases the urine commonly contains plenty of urobilin, which is probably a transformation product of bilirubin by the tissues. However, it must be noted that urobilinuria is commonly absent when bilirubinuria is marked. Latent jaundice may be present in heart disease and may suggest the onset of failure. Its presence will differentiate pernicious anæmia from secondary anæmia due to hæmorrhage. It may indicate damage of the liver after treatment with arsenobenzol, and in various infective diseases. It is very commonly present in cirrhosis.

Icterus Neonatorum. Jaundice is not infrequent in new-born children. It lasts only a few days or a week or two, and is unaccompanied by any symptoms. Bile pigment, as indicated by Van den Bergh's indirect test, begins to appear in the blood in measurable quantities at about the fifth month of intrauterine life, due to a physiological hæmolysis, and this process suddenly increases after birth, causing jaundice. The suggestion has been made that the maternal liver helps to prevent hæmolysis in the foetus, and that after birth the infant's liver is slow in taking up its full anti-hæmolytic function. (*See Pernicious Anæmia.*) The yellow colour affects first the face and trunk, and later the limbs ; and is recognised by

pressing the reddened skin, so as to exclude the blood colour. The fæces are generally normal, and the urine is untinted by bile pigment, except in the severer cases. The patients recover, and no treatment is required.

Grave Familial Jaundice of the Newly-born. This condition affects several members of the same family. Jaundice begins on the first day, occasionally the second day after birth, and rapidly increases in intensity. There is drowsiness and loss of weight. The infant dies about the fourteenth day, often with convulsions. The urine contains urobilin and often bilirubin; hæmorrhages are sometimes seen. The stools are normal in colour. The liver and spleen are sometimes enlarged. The *treatment* consists in giving intramuscular injections of 5 to 15 c.c. of the mother's serum into the buttock daily until the bile pigment in the blood diminishes. The serum is anti-hæmolytic. With this treatment the prognosis is good (90). Other cases of jaundice that must be distinguished are: *Familial acholuric jaundice*, in which "the patients are more icteric than sick"; *congenital obliteration of the bile ducts*, associated with white stools and biliary cirrhosis, and the liver is hard; *congenital syphilis*; *infective jaundice*, in which there is an obvious source of infection and the temperature is high.

ASCITES

By this term is meant the presence of serous fluid in the peritoneal cavity. Like other effusions into the serous cavities, it is commonly alkaline, of a pale straw colour, of specific gravity 1,015 to 1,018, highly albuminous, and containing chlorides. It arises (1) from obstruction of the portal circulation, either in the trunk of the portal vein, or in its distribution in the liver; (2) as a result of diseases of the peritoneum; and (3) as a part of the general dropsy of renal disease, or cardiac disease.

The portal vein trunk may be obstructed by the pressure of tumours and enlarged glands in the portal fissure, by carcinoma, abscess, or hydatid in the liver itself, and by coagulation of blood in its interior (*thrombosis, pylephlebitis*). In the liver the chief cause of portal obstruction is the compression of the interlobular veins by the fibrous overgrowth of cirrhosis. It is thought by some that portal obstruction is not an adequate cause of ascites, which they attribute to toxins produced in the diseased liver, or absorbed from the intestine and undestroyed by the liver. Another cause of portal obstruction is perihepatitis. A third kind of obstruction is formed by the different forms of cardiac and lung disease, in which the right side of the heart is dilated and the passage of the blood through the chest is impeded (*see p. 146*).

The peritoneal diseases causing ascites are—acute and chronic peritonitis, tuberculous peritonitis, and carcinoma of the peritoneum.

In Bright's disease the peritoneum is the seat of effusion, in common with the other serous cavities.

Physical Signs. The abdomen is enlarged, and in the early stages of a considerable ascites it is generally tense, and the form tends to be globular, with a decided prominence in a forward direction. Later the walls of the abdomen become stretched, and as the patient lies in bed the fluid gravitates backwards in each flank, and gives a broader and flatter shape to the belly. The liquid then poured out may amount to 3, 4, or 5 gallons, and the abdomen becomes proportionately enlarged so that it may measure from 40 to 42 inches or more in circumference. The presence of fluid is detected by three methods of examination—*percussion, fluctuation, and displacement*.

Percussion. Normally the surface of the abdomen is resonant from the air contained in the stomach and intestines; but when fluid is poured out this collects at first in the flanks and hypogastric region, so as to give a dull note to percussion in these parts, while the centre of the abdomen remains resonant. If the patient be turned upon one side and again percussed, it will be found

that the anterior and central regions have become dull, and the flank, which is now uppermost, gives a resonant note. This is due to the gravitation of the fluid to the lowest part and the floating of the air-containing bowel to the highest, and this occurrence is the most conclusive proof of the presence of fluid in the peritoneum and provides the most delicate test for ascites.

Fluctuation is obtained by laying one hand on one side of the abdomen and sharply tapping or flipping the other side with the finger. The applied hand then feels the transmission of a wave across the abdomen. This is a less certain sign than the former. Very fat abdominal walls may transmit a wave without the presence of fluid, and to prevent this the edge of the hand, or of a book or card, should be pressed on the centre of the abdomen while fluctuation is tried.

The method of *displacement* has only a limited application, but it provides in some cases earlier evidence of ascites than either percussion or fluctuation. If in a case of ascites the liver is enlarged, it sinks in the fluid, and a small quantity of fluid lies between its anterior surface and the abdominal wall. By placing the fingers on the abdomen at this spot, and suddenly pressing them in, the fluid is displaced, and the surface of the liver may be felt. This is a proof of the presence of fluid, since, if there were none, the liver would be in close apposition with the anterior abdominal wall.

Ascites is, however, sometimes simulated by one or other of the different kinds of cyst which may occur in connection with the abdominal or pelvic viscera, by a pregnant uterus, or by a distended urinary bladder. These cysts are ovarian, parovarian, hydatid, and renal cysts. They are excluded if the percussion test is successful; on the other hand, they may give the fluctuation test; and if the whole surface is dull there may be some difficulty in distinguishing between one of these and an ascites in which the intestines are bound down. An ovarian cyst is chiefly distinguished by the abdomen being dull in front and resonant in the flanks, into which position the intestines are pressed by the cyst, and by the swelling due to the cyst, which begins on one side, though later on it is central. Not infrequently also the outline of the cyst can be recognised at the uppermost part, especially if looked for during the movements of respiration.

Chylous and Chyliform Ascites. In exceptional cases the fluid contained within the peritoneal cavity is opalescent and milky instead of being a clear serum.

Sometimes this is due to the extravasation of chyle from the thoracic duct or lacteal vessels into the peritoneum, either from rupture or from obstruction of the vessels by disease or by the presence of parasites (*see* Filariasis). This is true *chylous ascites*. The fluid is then of a yellowish-white colour, has a specific gravity of 1,012 or more, and an odour dependent upon the food which is being taken. On standing fat separates and forms a creamy layer on the surface; fatty globules are seen under the microscope, but few cellular elements. A clot of fibrin may form in it after removal from the body.

In another group of cases, *chyliform ascites* or *pseudo-chylous ascites*, the fluid is pure milky white, of a specific gravity less than 1,012. The amount of fat is variable: it may form a creamy layer on the surface, or there may be only traces of it; but in any case the opalescence is not due to the fat, but to minute granules of a compound of lecithin and globulin, held in suspension by inorganic salts. Microscopically cellular elements containing fat may be present. The presence of lecithin enables this fluid to resist putrefaction for a long time.

These chyliform effusions are not distinctive of any one pathological condition; but in a large majority of the cases there has been found either carcinoma, or tubercle, or cirrhosis of the liver, or chronic nephritis; and generally the prognosis is bad.

Both chylous and chyliform liquid may occur simultaneously in other serous cavities; and there is no means of knowing, until paracentesis has been performed on one or other cavity, whether an effusion is of the kind under discussion.

DISEASES OF THE LIVER

ABSCESS

Pathology. Abscesses of the liver arise from the introduction of some septic agent by one of three channels: the hepatic artery, the portal vein, or the bile ducts in suppurative cholangitis (*q.v.*).

In the first case they form part of a general pyæmia, such as results from wound or injury in any part of the body, but especially injuries to the head; they are small in size, and numerous, or at least multiple. They are known as *pyæmic abscesses*.

The portal vein is responsible for a still larger number of cases, the septic agents being carried from lesions within the portal vein area, as described in suppurative pylephlebitis (*q.v.*) and tropical dysentery. The abscesses may be single, few, or multiple; and when they are multiple the condition may be spoken of as *portal pyæmia*. Sometimes the portal vein and its branches are filled with broken-down purulent clot, and the walls of the veins are inflamed, constituting *suppurative pylephlebitis*.

Abscesses of the liver vary in size from a pin's head up to that of a hazel-nut; they may contain well-formed pus, or sanious liquid and *débris*, or more bulky sloughs that have only just been separated. In cases originating in pylephlebitis it may be easy to show that much of the suppuration is in the course of the distribution of the portal vein. The capsule of the liver is frequently inflamed where abscesses approach the surface.

Symptoms. Cases of multiple abscesses in the liver are often very obscure, especially when they form a part of a general illness like pyæmia. There is severe constitutional disturbance, with fever of hectic type, rapid pulse, dry brown or furred tongue, and early prostration. Vomiting is often present, but the action of the bowels is variable: sometimes there is constipation, at others diarrhœa. The liver is mostly enlarged, and in some cases may reach to the level of the umbilicus; it is painful and tender. Jaundice is sometimes, but not necessarily, present; it probably requires the compression by an abscess, or the obstruction by gall stones, of some larger bile duct. The condition of the urine and of the fæces as to the bile pigment will, of course, vary with it. The duration of the illness is from one to several weeks, but the end is certainly fatal.

Diagnosis. This must depend on the fact that an enlarged liver is involved in an acute process, with severe general toxæmia, especially if these symptoms are associated with some lesion which can be recognised as the primary cause.

The **Treatment** must be mainly symptomatic. An attempt must be made to improve the general condition by nourishment, quinine, and stimulants. Opium and local applications, poultices, fomentations, etc., will be required to relieve pain.

COMMON INFECTIVE HEPATIC JAUNDICE

(*Catarrhal Jaundice; Acute Hepatitis*)

This is one of the commonest forms in which jaundice occurs. The name catarrhal jaundice arose from the belief that it was due to obstruction at the bile papilla with a small piece of inspissated mucus or swelling of the mucous membrane. It is not impossible that occasional cases may be due to such a cause.

Ætiology. Infective hepatic jaundice is especially frequent in early life. It may be associated with evidences of gastro-duodenal catarrh. It is usual to associate with it the well-known instances of jaundice from fright, the main features of which are, at any rate, similar.

Common infective hepatic jaundice has often been observed to occur in epidemics, known as *epidemic jaundice*. In many of these children are alone or

chiefly attacked ; in a smaller number of instances adults suffer most. Neither to the sporadic cases, nor to the epidemic cases, has a definite bacteriology been assigned, but where there has been opportunity to examine the gall bladder and bile passages these have been found to be empty of bile, indicating that liver secretion has failed, owing to acute hepatitis, which is doubtless the true cause of the condition. However, a duodenitis reflexly stops the outflow of bile and so may be responsible for some cases (76). Infectious jaundice, which is of leptospiral origin, is described elsewhere.

Symptoms. The patient may have indigestion, weight, pain, or distension of the stomach after food, with, perhaps, occasional sickness for three or four weeks before the jaundice ; and in other cases it may occur after unusual indulgence in particular kinds of food ; but in very numerous instances the patient knows absolutely nothing of his illness until he himself sees in the looking-glass, or is told by his friends, that his skin is acquiring a yellow tinge. Occasionally the jaundice is preceded by severe pains in the limbs, or the case progresses to become one of acute necrosis of the liver. The skin and conjunctivæ are of a bright yellow colour ; the urine is yellowish brown from bile pigment and contains ketone bodies ; the fæces are pale or clay-coloured. The serum usually gives Van den Bergh's direct test or a biphasic reaction. The temperature is generally normal, and there may be no constitutional disturbance, the patient being able to do his work as usual ; but often he is languid, indisposed for exertion, with a bad appetite, and some nausea. There is mostly no pain in the hepatic region, and not even tenderness ; but both may be present in moderate degree. The liver also is often not at all enlarged, but sometimes its dulness reaches one or two finger-breadths below the margin of the ribs, and the edge may then be felt, as well as the distended gall bladder. The bowels are variable, most often constipated, occasionally loose. The pulse may be unaffected, but it is especially in this form of jaundice that abnormally slow pulses have been recorded. The illness lasts from two to five or six or more weeks, and the jaundice gradually disappears, the urine becoming normal in colour first, and the skin more slowly recovering.

In the epidemic form the incubation period is from three to five weeks.

Diagnosis. It is occasionally possible to make the diagnosis before the onset of jaundice, since enlargement of the liver, which is an early sign, may suggest that functional efficiency tests for the liver should be carried out, and a functional deficiency may be found. The painless, or almost painless, onset of jaundice in a young person previously healthy, or at most suffering some gastric disturbance, as a rule, distinguishes it from the jaundice of *gall stones*, of *carcinoma*, and of *cirrhosis*, the other most common causes. If the jaundice lasts more than five or six weeks, the possibility of one of the above three diseases or of a more general cholangitis should be considered. The epidemic form must be distinguished from leptospiral jaundice (*q.v.*). The blood count may help. In the former, except possibly during the first few days, there is an increase of mononuclear cells, in the latter a polymorphonuclear leucocytosis.

Prognosis. With the rare exception of the onset of acute necrosis, this is entirely favourable.

Treatment. The patient need not be confined to bed, unless there is fever ; but should take a diet with plenty of carbohydrates, especially glucose, and avoid fats and stimulants ; and a saline laxative should be given if necessary.

ACUTE NECROSIS OF THE LIVER

(*Acute Yellow Atrophy*)

In this remarkable disease the liver undergoes a rapid degeneration of its tissues, and diminishes in size to two-thirds, or even one-half, of its normal bulk.

Ætiology. It is more common in females than in males, and the majority

of patients are under thirty years of age, though it is very rare in children. Indeed, at any age it is a disease of extreme rarity. Its onset is often preceded by severe mental disturbances, and many of the cases have occurred in people who have led a dissipated life, in the subjects of syphilis, and in women who are pregnant. It has also occurred within twenty-four or forty-eight hours of a surgical operation; this has mostly been an abdominal operation, performed under chloroform. Acute necrosis, giving rise to toxic jaundice, results from poisoning with trinitrotoluene (T.N.T.), tetrachlorethane (aeroplane dope), arsenobenzol derivatives (see p. 117), phenyl-cinchonic acid (see Gout), and in cases of leptospiral jaundice. Acute necrosis on the one hand and cirrhosis of the liver on the other may be different phases of essentially the same process, viz., poisoning of liver cells, in the one case acute, in the other extremely chronic. Further, there is a whole series of cases of *subacute atrophy*, or *multiple nodular hyperplasia*, that bridge the gap between the two. Again, its infective origin in some cases, from common infective jaundice, has already been mentioned. The biochemical changes are described under Liver Function.

Morbid Anatomy. 1. *The Acute Type.* In the most acute cases the liver is large and canary yellow in colour. When the disease is not quite so acute the liver is very much diminished in size; it may be only 30 or 28 ounces in weight. It is soft, flaccid, almost like a bag of fluid, and its capsule, which is wrinkled, appears too large for its contents. On section the liver is of a yellow colour, with patches of rather bright red; or in some parts it is entirely red, in others all yellow. The essential change is a granular and fatty degeneration, by which the hepatic cells are more or less completely destroyed. The necrosis begins in the central zones of the lobule. In the yellow parts of the liver the destruction is less advanced, and some bile-stained cells may still perhaps be found. In the red parts the colour is due to the more complete necrosis of the tissue, by which the vessels are left alone to represent the substance of the liver. Under the microscope one can often see nothing but granules of albuminous matter, fat and pigment, and larger globules of fat. Leucin and tyrosin are also found in the liver, and will spontaneously crystallise on the surface of sections some hours after death. The bile ducts are empty, and are stained by bile pigment: the gall bladder is also empty, or contains a small quantity of viscid grey mucus.

Other organs undergo fatty degeneration, especially the kidneys, in which the secreting cells are granular and fatty, and the heart and muscles. Petechiæ are found under the skin, in the mucous membranes, under the serous membranes, in the kidneys, and other parts.

2. *Subacute Atrophy, or Multiple Nodular Hyperplasia.* The liver is not so much reduced in size, and regeneration of liver tissue is the chief feature. Adenomatous-looking nodules, yellow in colour, are seen set in a stroma of fibrous tissue. They may be small or large, depending on the amount of regeneration, and microscopically they contain newly formed liver cells and bile ducts, though necrotic cells are also present in abundance. To the naked eye the liver has a curious appearance, the arrangement of the fibrous tissue being similar to cirrhosis, and the yellow nodules resembling in appearance the acute form of the disease.

Symptoms. The symptoms are at first obscure. Often it begins with a jaundice indistinguishable from catarrhal jaundice, or with gastro-intestinal symptoms, such as nausea, vomiting, and irregularity of the bowels; and pains in the hepatic region may occur comparatively early. These symptoms may last two or three weeks, or much longer when the more characteristic features develop. These consist of marked cerebral disturbances—at first headache and restlessness, then delirium and gradually developing coma, with convulsive twitchings, or more rarely epileptiform fits, towards the end. Jaundice then appears, or if it has been present early it becomes deeper. The blood serum may give either a direct, indirect or biphasic reaction with Van den Bergh's test. The

temperature is rarely high, but may be from 101° to 102°. The pulse, which may have been slow with the early jaundice, now becomes quick. The tongue is dry and brown, and as the symptoms progress sordes collect about the lips and teeth. There is, besides, pain in the hepatic region, and decided tenderness, which may be recognised even during the stage of coma, if pressure be made there. The extent of dulness diminishes with great rapidity, so that finally its vertical measurement is only an inch or less.

The abdomen is natural, or towards the end it is retracted. The spleen is mostly enlarged. The urine contains bile and not infrequently albumin, especially towards the end, and casts; and there may be also blood, the indication of a general hæmorrhagic condition which may be further shown by coffee-ground vomit; by the fæces, which appear to be mostly pale, and deficient in bile, containing blood; and by epistaxis, metrorrhagia, or petechial hæmorrhages under the skin. With increasing coma death finally takes place, the severer symptoms lasting only from two to four days. Pregnant women, as a rule, abort.

Sometimes a case lasts a much longer time, several months or two years, and these cases have been called *subacute atrophy*. In other cases the attack is quite mild, and the patient recovers. In fact, in cases of T.N.T. and arsenobenzol poisoning it is only the worst cases that die. It was formerly believed that acute yellow atrophy was almost invariably fatal; but these cases of recovery prove that a mild form of the disease does exist. There is often a remarkable latency in the T.N.T. poisoning cases, since jaundice may only be noticeable some years after exposure to the poison has ceased.

Diagnosis. This depends upon the occurrence of cerebral symptoms and rapid diminution of hepatic dulness in a jaundiced patient. X-ray examination is a valuable method of diagnosis (Strathy and Gilchrist). In the vertical position there is a diminution in the height of the shadow. The upper surface is more dome-shaped owing to relaxation of the capsule and traction of the lung, and the lower border is rather more vertical than normal.

Prognosis. Acute necrosis when the symptoms are developed is exceedingly fatal; but cases have temporarily improved, to relapse and die later. These are the subacute cases. The milder cases may recover completely.

Treatment. In the final stage little can be done; but in the earlier stages attempts may be made to remove or neutralise the toxic factor, and so possibly prevent the further progress of the disease. Rest in bed, the administration of glucose by mouth (10 per cent.) and intravenously (6 per cent.), of 10 per cent. calcium gluconate intravenously (10 c.c. daily), and of sodium thiosulphate intravenously (0.6 gram) with abundance of fluid should be tried.

CIRRHOSIS OF THE LIVER

The name *cirrhosis* is given to diseases of the liver where there is infiltration with fibrous tissue. The name *cirrhosis* (*κίρρος*, yellow) was used owing to the general yellow colour of the liver in portal cirrhosis, and not in reference to the presence of excess of fibrous tissue. Nevertheless the name has been often applied to chronic fibrous changes in other organs of the body—*e.g.* cirrhosis of the lung and cirrhosis of the kidney; but the term “fibrosis” is much to be preferred for these organs.

There are *three* chief types of cirrhosis: (1) *portal cirrhosis*, in which chronic irritants reach the liver through the portal vein and in which circulatory disturbances causing gastric hæmorrhage and ascites are the prominent clinical features; (2) *biliary cirrhosis*, in which jaundice is the prominent feature, and ascites occurs only as a terminal condition; (3) *pericellular cirrhosis*, occurring in congenital syphilis (*see p. 397*).

PORTAL CIRRHOSIS

(Multilobular, Alcoholic Cirrhosis, Hobnailed Liver)

Ætiology. In the great majority of cases portal cirrhosis is dependent, wholly or in part, upon the excessive use of alcohol, in the form of beer, wine or spirits. Little is known as to the amount that is required to produce cirrhosis; there are the widest individual differences. Some people may drink freely all their lives without acquiring it, whereas in others a few months' indulgence seems sufficient for the purpose. In some children that have been the subjects of it the fact of alcoholism has been proved. But there are cases of undoubted cirrhosis of the liver in which alcohol as a cause can be certainly excluded. It is possible also that intestinal toxins may cause some forms of the disease. The cirrhosis due to syphilis is considered later. Some slight degree of fibrous overgrowth may result from chronic heart disease, but this is not cirrhosis as ordinarily understood. Cirrhosis of the liver occurs as a late result in some cases of splenic anæmia (*see* Anæmia), and the cases are then described as *Banti's disease*.

A large-livered cirrhosis is also associated with pigmentation in cases described as *hæmochromatosis*. Iron pigment in the form of hæmofuscin and hæmosiderin (the latter gives the Prussian blue reaction—Perl's test) is deposited in large amounts—ten times the amount normally present in the whole body—in the liver and in the pancreas, but also in other organs, voluntary muscle, celiac lymph glands and skin, producing bronzing; it is uncertain whether the cirrhosis precedes or follows the pigment in the liver; in bronzed diabetes—*diabète bronzé*—diabetes follows upon the deposition of hæmosiderin in the pancreas. It has been suggested that hæmochromatosis results from prolonged copper poisoning.

The tropical infectious disease, Kala-azar, is accompanied by a moderate degree of cirrhosis; a somewhat similar combination of cirrhosis, enlarged spleen and bone marrow changes, but without the Leishman-Donovan bodies, is endemic in Egypt (Day and Ferguson); and a curiously localised portal cirrhosis is found as a result of bilharzia infection (*see* Bilharziasis).

Morbid Anatomy. The organ varies much in size; it may be very large, or about the normal size, or very much smaller: in the former case, sometimes called *hypertrophic* cirrhosis, the surface may be fairly smooth or present rather fine granulations; in the latter case, sometimes called *atrophic* cirrhosis, the shape is often much altered from the extensive and irregular contraction of the fibrous tissue, which forms coarse knobs on the surface (hobnailed liver). When ascites has constantly reappeared during life, after tapping, the capsule of the liver is found to be thickened (*see* Perihepatitis). In all cases the organ is very much tougher and harder than normal, from the development of fibrous tissue, which runs in all directions through it. The liver presents on section a number of yellow, brownish-yellow, or brown areas surrounded and separated from one another by broad tracts of grey translucent fibrous tissue. If it can be examined in the earliest stages of cirrhosis, there are found large numbers of round cells infiltrating the tissue about the portal canals (Glisson's capsule), and in some cases penetrating more or less between the lobules, or even within them. Later on white fibrous tissue is developed, which forms a large part of the section in an advanced case. The bands of fibrous tissue running through the organ break it up into islands of hepatic tissue, each of which may consist of several lobules (*multilobular cirrhosis*); but the fibrous tissue not infrequently breaks right through a lobule, and sometimes single lobules are surrounded by it. There is great variety. The cells are atrophied and mostly stained yellow or brown by pigment granules. In the fibrous tissue are numerous newly formed blood vessels, which can be injected from the hepatic artery, and regenerating liver cells are also seen. In fact, the production of cirrhosis may be looked upon as the attempt of the body at repair, which follows necrosis of the middle and outer

zones of the lobule. The newly formed, highly vascular, fibrous tissue is an advantage since it supplies nutriment to the regenerating liver cells (78). Later on it becomes useless when it contracts, and thus compresses more and more the hepatic cells, the branches of the portal vein, and perhaps the bile ducts. The organ is at first enlarged by the overgrowth of connective tissue, and some large cirrhotic livers also contain a quantity of fat. The liver cells and fat may eventually disappear, and the organ may be reduced much below its normal weight. The varying size of the liver is thus, in part at least, dependent on the stage of the process.

Cirrhosis carcinomatosa is the name given to cases in which a primary carcinoma develops in a cirrhotic liver (*see* p. 400). It presumably results from the chronic irritation—in the same way as an epithelioma of the tongue follows a chronic syphilitic glossitis.

Symptoms. The symptoms of portal cirrhosis are mainly due to increasing obstruction of the portal circulation. Jaundice and other signs of hepatic deficiency are often absent or come on late in the course of the disease. The serum may give Van den Bergh's biphasic reaction. There is frequently, as a result of free drinking, a gastritis which produces loss of appetite, furred tongue, and vomiting, especially in the morning. An examination of the abdomen at this stage may, however, reveal a considerable enlargement of the liver, of which the patient is entirely ignorant. The next symptom is not infrequently *hæmatemesis*; this is due to the commencing obstruction in the portal circulation; as the blood in the portal vein finds a difficulty in passing through the liver, the radicles of this system, viz. the mesenteric, gastric, and splenic veins, are, of course, congested, and tend to bleed on to the mucous surfaces. But sometimes the blood proceeds from a rupture of the veins at the lower end of the œsophagus, which have become varicose in the course of establishing a free communication between branches of the portal vein and branches of the inferior cava vena or azygos vein. The *hæmatemesis* may be followed by *melæna*. Piles are not infrequently present at the same time, and hæmorrhage from other parts (gums, nose, and lungs) is liable to occur in the course of cirrhosis.

The most important and constant result of the portal obstruction is the effusion of fluid from the distended veins into the peritoneal cavity, constituting the form of dropsy already described as *ascites*. In many cases, when ascites has developed, the liver is still enlarged, and can be felt 1 or more inches below the ribs; the edge is firm, and very sharp or rounded, but the surface will be smooth if there is much perihepatitis; but it is commonly granular or nodular. The spleen is often enlarged and palpable. The surface of the abdomen is covered by large veins, running between the iliac and thoracic trunks. This collateral circulation is a means by which the portal circulation is relieved. This is an important point, for it must be remembered that the portal system is not completely shut off from the general circulation, but that there are, even in health, means of communication which in cirrhosis become greatly enlarged, and allow of some of the blood in the portal vein radicles reaching the right side of the heart without passing through the liver itself. Those which have been described are communications (1) between the gastric and œsophageal veins at the opening in the diaphragm; (2) between the inferior mesenteric and the hæmorrhoidal branches of the internal iliac vein; (3) between the coronary veins of the stomach and branches of the phrenic veins; (4) between branches of the mesenteric vein and the spermatic vein, or others in the abdominal wall. Frerichs described (5) vessels forming in the adhesions between the liver and the diaphragm; and (6) a large vein (accessory portal of Sappey) has sometimes been found running along the round ligament of the liver, by which the portal vein communicates directly with branches of the epigastric and internal mammary.

The bases of the lungs are often seriously compressed by a large ascites. Hydrothorax and œdema of the legs often occur. By the time that ascites is

well developed the patient is in other respects often seriously ill. He is thin, weak, with sunken eyes, a slight tinge of jaundice, and small stellate venules on the face. The temperature is mostly normal, but fever is sometimes present. Death may result within a few months of the appearance of ascites, with cardiac failure, or with cerebral symptoms (delirium and coma) from chronic alcoholism. Occasionally hæmatemesis is fatal. Secondary infections, such as peritonitis, also commonly cause death.

Diagnosis. Cirrhosis is often latent until hæmatemesis, ascites, or slight jaundice discloses the secret, or its onset may be suspected owing to alcoholic habits, and may be proved by a positive lævulose or galactose tolerance test. Examination may discover an enlarged rough liver in a tippler who has no decided trouble. Most commonly the diagnosis has to be made when ascites has already appeared, and then the history of drinking and of hæmatemesis, the presence of an enlarged liver, enlarged spleen, and slight jaundice, are sufficient to determine the case. Of the other conditions of the liver and peritoneum causing ascites the most important are *carcinoma*, which may obstruct the portal vein, or its largest branches, and the association of *perihepatitis* with *chronic thickening of the peritoneum* (see *Perihepatitis*). *Carcinoma* and *tubercle*, apart from the liver, also cause a peritonitis, which results in ascites. The former may be recognised by the occurrence of nodules of growth in different parts of the abdomen. The latter often presents a thickening of the omentum, which may be mistaken for an enlarged liver. Hæmatemesis is frequently the result of cirrhosis, and is valuable in diagnosis; but it also commonly occurs in acute gastric ulcer and splenic anæmia.

Prognosis. In the early stages, especially if the condition has been disclosed by a functional test, the prognosis is good if alcohol is stopped. When ascites has developed the patient may still live for some years with repeated tappings. In some cases in children ascites has occurred as the first symptom, and yet the patient has lived for eight or ten years.

Treatment. Little, if anything, can be done with the cirrhotic liver itself; and treatment resolves itself into the prevention of further mischief, and the attempt to obviate the effects of the damage already done. In alcoholic cirrhosis the first essential is that the ingestion of alcohol should be absolutely stopped; and in early stages the liver may become normal again. It is, however, impossible in such a case to say how far fibrosis has progressed. The diet should contain plenty of carbohydrate, and proteins should be restricted; the bowels should be kept active, and sickness and any dyspeptic symptoms may be treated as previously described. When ascites occurs it has been considered unsafe to cause its disappearance by diuretics such as salyrgan, because of the toxins it contains, though these have often been employed. Of purgatives sulphate of magnesium, bitartrate of potassium, compound jalap powder, or elaterium may be employed. When the abdomen becomes very tense, paracentesis is required, and it may sometimes be repeated with success as the fluid reaccumulates. Attempts to develop a collateral circulation based on the view that ascites is mainly mechanical in origin have been made (1) by opening the abdomen, scraping the peritoneum on the opposed surfaces of the liver and diaphragm, and bringing them into contact by stitches (Drummond and Morison, Talma), and (2) by uniting the great omentum to the anterior abdominal wall (*epiplopexy*). It is even claimed that 30 per cent. of these operations have met with some success.

BILIARY CIRRHOSIS

1. **Hanot's Cirrhosis** (*Hypertrophic Biliary Cirrhosis*). The ætiology of this disease is obscure. It is not known whether the liver parenchyma or the bile ducts are primarily affected. It is a rare disease, commoner in males than females, and often occurring in children. There is considerable enlargement of the liver, and often in children still greater enlargement of the spleen, stunted

growth of the patient, deep pigmentation of the skin, and marked clubbing of the finger ends (*splenomegalic cirrhosis*). Jaundice is a marked feature of the disease, and the urine contains bile pigment, whereas ascites is not present until just at the termination. The disease may last for several years. Towards the end the patient becomes delirious, even violently so, and relapses into coma. The temperature is high, hæmorrhages occur under the skin and from the mucous membranes, and he dies in three or four days.

The liver, besides being smooth and large, is deeply stained with bile on section. The fibrous tissue is much more delicately arranged than in portal cirrhosis, each lobule being surrounded by fibrous tissue (*unilobular cirrhosis*). Some fibrous tissue may also be present inside the lobule round the liver cells. There is marked proliferation of bile ducts. There is evidence that a large cirrhotic liver may become smaller during the patient's lifetime. Sir Frederick Taylor recorded a case in which a liver reaching below the umbilicus, in a patient with strongly marked jaundice and no ascites, was found fifteen months later to have contracted quite close under the edge of the ribs. The treatment is described under Portal Cirrhosis.

2. Obstructive Form. Experimentally Rous and Larimore have produced a pure unilobular cirrhosis similar to Hanot's cirrhosis by ligaturing one of the bile ducts and the corresponding branch of the portal vein. The amount of bile formed was less than before, but being unable to pass along the usual channels, it passed out through the walls of the interlobular ducts, causing irritation and fibrous tissue formation.

Again, by ligaturing the other branches of the portal vein instead, all the portal blood was diverted to the area of the liver where there was biliary stasis. A larger amount of bile was formed, which escaped out of the intralobular bile canaliculi, giving rise to a pericellular cirrhosis.

These results have naturally a great bearing on the pathology of Hanot's cirrhosis, suggesting that it may really be due to obstruction of the smaller bile passages. There exists, however, a form of obviously obstructive biliary cirrhosis, which is sometimes, but not always, met with clinically, when there is long-continued obstruction of the bile ducts due to gall stones or carcinoma, etc. The bile ducts are seen to be greatly dilated, and the liver may show unilobular, or sometimes multilobular, cirrhosis. The treatment consists in removing the cause as far as possible by surgical methods.

SYPHILIS AND TUBERCULOSIS OF THE LIVER

Syphilis may be *congenital* or *acquired*.

Congenital Syphilis occurs first as *pericellular cirrhosis*, secondly as gumma. The former change begins as a cellular infiltration, which develops into a fibroid induration; it invades the lobules, and surrounds each cell with a layer of fibrous tissue, leading to considerable enlargement of the organ. Microscopic examination may also show: (1) increased fibrous tissue round the portal canals (*periportal cirrhosis*); (2) numerous embryonic red cells, due to the liver continuing its hæmatopoietic functions, which may help to compensate for the destruction of corpuscles by the syphilitic toxin; (3) miliary gummas (80). Spirochætes are present in the connective tissue. The spleen is often enlarged at the same time. Jaundice occasionally occurs, but ascites rarely. A multilobular cirrhosis has sometimes developed in those previously the subjects of the intercellular form.

Treatment. See Congenital Syphilis, p. 117.

Acquired Syphilis. The jaundice that is not infrequent in the early stages of syphilis, and was known before the introduction of arsenobenzol compounds, shows that this infection may produce an acute hepatitis. In the later stages syphilis produces gumma of the liver. This presents the general features of gumma in other situations, and spirochætes are found. They are more or less spherical yellow masses, tough and elastic, surrounded by a zone of grey

fibrous tissue, from which branch off numerous bands into the adjacent hepatic substance. The contraction of the fibrous tissue produces a depression or fissure on the surface of the liver, at the bottom of which lies the gumma which has caused it; and so the organ may become coarsely lobulated and deformed. Gummas not infrequently break down in the centre into a puriform detritus; on the other hand, they may become completely fibrous, so that nothing remains but a depressed scar; or calcareous granules may be deposited in them. Gummatous livers often become lardaceous, and in consequence they may be of large size in spite of cicatricial contractions. Perihepatitis is another change resulting from syphilis. It is probable that syphilis is responsible for some cases of multilobular cirrhosis.

Symptoms. Occasionally a large gumma may form a prominence on the anterior surface of the liver, smooth and elastic, and strongly suggestive of a hydatid or other cyst; it may cause elevation of the right costal margin. More often, but probably in later stages, syphilitic livers are large, hard, irregular on the surface, and deformed, from the contraction of the fibrous cicatrices. Neither ascites nor jaundice is necessarily present, but in particular cases they may occur from the pressure of a gumma upon the portal vein or the bile duct; and there is often albuminuria from co-existing lardaceous disease of the kidney. A gumma is sometimes accompanied by decided fever of hectic type.

Treatment. In early cases, iodide of potassium will quickly reduce the gumma and check the fever accompanying it; salvarsan may also be tried cautiously, the patient being given plenty of carbohydrate. But when there are old cicatrices and lardaceous disease, little good can be expected.

Tuberculosis. This is almost invariably a part of a general tuberculosis. (See Miliary Tuberculosis, p. 163).

NEW GROWTHS IN THE LIVER

The only tumour of the liver that is at all common is carcinoma. Of others cavernous angioma, simple cysts, and the lymphadenomatous deposits associated with Hodgkin's disease are the most frequent. They rarely cause definite symptoms. Cases of spindle-cell sarcoma, melano-sarcoma, cysto-sarcoma, myxoma, and adenoma have been recorded.

FATTY LIVER

Fatty Infiltration. The hepatic cells normally contain a small quantity of fat. Under certain conditions the neutral fat is immensely increased. **Fatty Degeneration.** In this condition there is a change in the physical characteristics of the fat; it may be seen histologically as globules in the cells, which are degenerated in consequence.

Ætiology. There are a large number of causes of fatty infiltration and degeneration; these include pregnancy and lactation; general obesity; starvation; congestion of the liver in heart failure; untreated diabetes; eclampsia; febrile conditions, where the toxins and high temperature damage the cell; severe anæmias; acute necrosis and other disease of the liver; poisoning by phosphorus, arsenic, carbon monoxide, chloroform, phenyl hydrazine, carbon tetrachloride, etc.

Pathology. The fatty liver is much enlarged; it has a smooth surface, is somewhat rounded at the edge, on section has a whitish-yellow colour and uniform appearance, and it may actually float in water.

Symptoms. The fatty liver is painless; it may be difficult to feel as it is of soft consistence, though large and smooth; and also the abdominal wall may be fat. In general the symptoms are those of the causal condition. In particular the section on Obesity should be consulted.

Experimentally, it was observed that in depancreatized dogs the diabetes often apparently improved with lapse of time; less sugar was passed and yet the

animal eventually died and a fatty liver was found; the animals remained healthy if raw pancreas was given by mouth. It is possible that the substance in the pancreas which is responsible for the cure is choline (79).

LARDACEOUS DISEASE

(*Amyloid Disease*)

Lardaceous degeneration has been already referred to in connection with empyema and phthisis; and as the liver is one of the organs which are most frequently implicated, a short account of the degeneration must here be given. It consists in the deposition in the tissues of a firm, colourless, translucent protein material containing much tyrosine (*lardacein* or *amyloid*), which is stained by certain colouring agents. Thus iodine in aqueous solution turns it a rich brown-red mahogany colour. The iodine may be applied to a section of the fresh organ after this has been washed free of blood, and the affected parts are then mapped out by the characteristic tint. The subsequent addition of dilute sulphuric acid changes this to a dark purple hue. Methyl-violet or gentian-violet turns lardaceous matter red, while the surrounding healthy tissue is stained blue.

The tissues in which it is found are, first in point of time, the walls of the blood-vessels; secondly, various connective tissues; and lastly, if at all, the gland cells of an organ. Indeed, the material is mostly intercellular in its position: thus it is found in the small arteries deposited between, and separating from one another, the muscle fibre cells of the middle coat; in the spleen it exists as streaks and patches between the cells of the pulp; and in the liver it lies in similar particles between the capillaries and the gland cells. It is, indeed, not so much a degeneration as an addition to the structure; and solid organs affected by it are generally much enlarged. Its relation to the vessels suggests that it is deposited from the blood. It occurs most often in the spleen, kidneys, liver, intestines, and stomach, and with decreasing frequency in the suprarenal capsules, lymphatic glands, thyroid, aorta, ovaries, and uterus. It is due to prolonged suppuration in any part of the body and it is specially common in phthisis, tertiary syphilis, tuberculous disease of bones and joints, and empyema, or in syphilis, without suppuration.

In the *liver* the lardaceous change is first observed in the middle zone of the lobules, where the capillaries are most intimately connected with the divisions of the hepatic artery. As the deposit increases the hepatic cells are compressed and atrophied, but they are only occasionally the seat of lardaceous deposit. The liver becomes enormously enlarged, has a smooth surface and somewhat rounded edge, and is entirely free from pain or tenderness. The disease causes no jaundice. It is accompanied by the signs of the causative disease, and often by an enlarged spleen, albuminuria and diarrhoea, the results of the deposit in other organs. A lardaceous liver, which is at the same time the seat of a syphilitic gumma or cicatrix, naturally loses its uniform smooth surface, but may be recognised by its other associations. The portal circulation is not obstructed by lardaceous change alone, and although ascites is not infrequently present, it is mostly associated with general anasarca, and must be referred with it to co-existing disease of the kidneys, or it may be due to other complications, such as cirrhosis, gumma, or chronic peritonitis. Lardaceous disease of the *kidney* often produces the appearance of large white kidney. On microscopic examination the glomerular tuft is often first altered, then successively the vasa afferentia, the vasa recta, the vasa efferentia, and the intertubal vessels. In some cases, however, the change can be found in the vasa recta before it is seen in the glomeruli. There are, in addition, the inflammatory changes of large white kidney. The lardaceous *spleen* is enlarged, hard and smooth. The change affects the splenic vessels and the Malpighian corpuscles, which last

appear as grey specks upon the surface (*sago spleen*) ; in other cases the lardaceous material is deposited between the cells of the pulp, and the organ is more uniformly pale.

The **Diagnosis** has been made by means of liver puncture. The presence of albuminuria in a case having a long-continued suppurating lesion or tertiary syphilis will suggest the possibility of the disease, especially if the spleen or liver is also enlarged. The urine may contain a few hyaline or granular casts, and, rarely, some which give the lardaceous reaction. If the functions of the kidneys are much interfered with the case may closely resemble any type of Bright's disease and there may be diarrhoea from co-existing lardaceous disease of the intestine.

Prognosis. This is very bad, but decrease of the enlargement of the liver after efficient surgical treatment has been recorded. Death may take place from increasing dropsy, uræmia, exhausting diarrhoea, serous inflammations, or hepatic insufficiency.

Treatment. The cause must be, if possible, removed. This is impracticable in phthisis, but other sources of suppuration may perhaps be treated surgically ; and potassium iodide, cod-liver oil, iron, quinine, and other tonics should be given. Mercury and potassium iodide should be used in syphilitic cases.

CARCINOMA OF THE LIVER

Pathology. Primary carcinoma occurs in two forms—as nodules appearing in any part of the liver and as a diffuse infiltration. Histologically carcinoma of the liver is of two kinds, consisting of (1) liver cells, which may secrete bile, or (2) bile duct cells. Primary carcinoma occasionally develops in a cirrhotic liver. The liver is not, as a rule, much enlarged ; it presents, besides the fibrous overgrowth, multiple tumours which are at first firm and white, but later degenerate or undergo necrosis, and acquire a yellow or green colour. The clinical features are those of cirrhosis, and the condition has been called *cirrhosis carcinomatosa*.

By far the greater number of cases of carcinoma of the liver met with are secondary to carcinomatous deposits in other organs, especially the stomach, the intestine, the gall bladder, the glands in the portal fissure, the uterus, or the breast. The carcinoma cells are carried to the liver by branches of the portal vein, and lodged in the lobular capillaries. The form of the secondary carcinoma, whether soft or hard or melanotic, is determined by the nature of the primary growth.

If the carcinoma is diffused, the liver is merely enlarged ; but when it exists in the form of nodules, or separate tumours, the liver takes at the same time the most varied shapes. Each nodule tends to grow evenly in every direction, and thus to keep a globular form, and when it reaches the surface it will project as a hard, convex, or hemispherical outgrowth. But as the nodules become larger—for instance, $1\frac{1}{2}$ to 2 inches in diameter—they often break down in the centre into granular and fatty detritus, and as a consequence those that project on the surface, being unsupported on one side, sink in and form a central depression or *umbilication*, a condition which may sometimes be felt through the anterior abdominal wall. The lower edge of the liver is also irregular and nodulated. On section such a liver presents irregular areas of white carcinomal growth, with a more or less circular outline ; the larger ones are softening in the centre, and many of them are blotched by hæmorrhages. The intervening hepatic tissue is often of a deep brown or yellow colour. Where the carcinoma has started from the gall bladder, or the bile duct, or has grown in from the portal fissure, the growth is most extensive in that region, or may be quite confined to it. Sometimes the empty gall bladder, or a gall bladder containing some calculi, is embedded in a mass of carcinoma. Carcinomatous nodules near the portal fissure may compress the bile duct or the portal vein, and the latter may be entirely filled by the new growth.

Symptoms. Carcinoma of the liver usually gives rise to a good deal of pain, affecting the right hypochondrium, shoulder, and loins. At first not much more than a sense of weight and uneasiness, it afterwards becomes severe and lancinating, and is accompanied by tenderness. Occasionally, however, pain is absent. The liver, as already stated, is enlarged; it may reach far below the umbilicus, and over towards the left side; the nodules are prominent on the surface, and the irregular outline may even be seen in profile. For the most part the enlargement is in a downward direction, but large masses may grow from the convex surface, and force up the diaphragm so as to compress the base of the lung. The surface of the carcinomatous mass is, as a rule, of almost stony hardness, distinctly more hard than cirrhosis, or lardaceous disease, and the transition from hard carcinoma to the soft normal tissue can often be recognised. Jaundice occurs in about half the cases and can generally be shown to result from pressure on the main bile duct, especially in those cases where the carcinoma starts from the portal fissure. Van den Bergh's direct test is given. Similarly, ascites is often, but not always, present, and rarely is the fluid as abundant as it may be in cirrhosis. It mostly depends on direct pressure on the portal vein or its large branches, occasionally on a co-existing peritonitis. The emaciation, pallor, and prostration common to malignant diseases of the abdominal viscera are also present. Pyrexia occurs in many cases of carcinoma of the liver, and occasionally it has exacerbations and remissions like those seen in Hodgkin's disease.

Diagnosis. A jaundice of some months' standing in an old person with an enlarged liver is, in the majority of cases, due to carcinoma of the liver or of the head of the pancreas, though occasionally the bile duct may be obstructed permanently by a gall stone. If hard, irregular nodules are felt on the surface of the liver, the diagnosis of hepatic carcinoma is highly probable; the prominence due to gumma is generally solitary, an inch or more in diameter, and soft or elastic. If the liver is of uniform and not very great hardness, carcinoma is only probable. In cases without jaundice, the large, irregular, and bossy liver and the emaciation of the patient are generally distinctive. Lardaceous and cirrhotic livers are less hard and more uniform. In both these cases the spleen is frequently enlarged also, in the first case by lardaceous deposit, in the second by venous stagnation, whereas carcinomatous enlargement of the spleen is relatively uncommon. Syphilitic livers may be irregular and painful, but often occur in younger people, and have their own special history. A long history of gall stones does not exclude, but rather favours, the possibility of carcinoma.

Prognosis. This is hopelessly bad. The duration is rarely more than twelve months, but may be two or three years. The softer forms of growth may kill within a month or two.

Treatment. This can be only palliative, and consists in relieving pain and in meeting other symptoms, mostly of the digestive organs, such as vomiting, flatulence, and constipation. The diet should be light but nutritious.

CYSTIC DISEASE

In this uncommon condition there are numerous cysts, more or less aggregated together, varying in size up to an inch or more in diameter, containing a clear or yellowish-brown watery liquid. It is very frequently associated with cystic disease of the kidneys and other organs. The liver may be enlarged, but otherwise there are no symptoms, and its diagnosis, prognosis and treatment are dependent upon the like change in the kidneys with which it is associated (see Cystic Disease of the Kidney).

PERIHEPATITIS

Pathology. Perihepatitis, or inflammation of the capsule of the liver, may be acute or chronic, localised or more generally diffused. It is set up by

any lesion which occurs in and about the liver, especially cirrhosis, syphilitic disease, cholecystitis, carcinoma, hydatid, and subphrenic abscess, and it may be part of a general peritonitis.

In acute perihepatitis the appearance of the surface of the liver is one of acute peritonitis. In chronic perihepatitis the capsule is opaque and more or less thickened; often the thickening is distributed in patches irregularly over the surface; and such patches may be determined by the disease which causes the inflammation of the capsule. Sometimes the liver is completely enclosed in a thick casing, from 2 to 10 mm. in thickness (German *Zuckergussleber*, sugar-icing liver). In such cases the organ has a rounded anterior edge. In the severer forms ascites is generally present, the result of the accompanying peritonitis, and the spleen is often similarly affected (*perisplenitis*).

Symptoms. In acute perihepatitis there is local tenderness and pains, especially on respiration, while a friction sound may be heard, or a rub can be felt on laying the hand over the liver. In chronic cases the liver is hard and recurrent ascites may be a feature. The underlying cause should be treated.

PYLEPHLEBITIS

This occurs in two forms, adhesive and suppurative, which have been already referred to, the one as a cause of ascites, the other in connection with multiple abscesses of the liver (*see* p. 390).

ADHESIVE PYLEPHLEBITIS

This is more generally a thrombosis of the portal vein, in which the clot adheres to the wall of the vein, and becomes ultimately organised in the same way as a thrombus in any other situation. Its causes are those changes which bring about retardation of the blood current in the portal vein or its distribution, such as cirrhosis, syphilitic disease, the pressure of tumours on the trunk of the vein or its implication in perihepatitis, or chronic peritonitis near the fissure of the liver. The obstruction to the portal vein leads to a form of Banti's disease, viz. splenic anæmia combined with cirrhosis of the liver.

SUPPURATIVE PYLEPHLEBITIS

This is nearly always due to infection from lesions in the abdomen—i.e. the area from which the blood is supplied to the portal vein—such as appendicitis (the most common cause), ulcers of the rectum, colon, or small intestines, gastric ulcer, and any suppuration in the abdomen or pelvis. In the new-born child the portal vein may be infected from a septic phlebitis of the umbilical vein, and rarely the lesion may be initiated by direct injury.

The mischief commonly begins in the peripheral branches of the portal vein. The wall of the vein inflames and suppurates, a thrombus forms, breaks down into pus, and its conveyance to the central branches in the liver sets up fresh centres of thrombosis, phlebitis, and suppuration. Finally, in many cases, multiple small abscesses of the liver are formed. The liver is enlarged and soft. The branches of the portal vein are filled with disintegrating thrombi, or pus, or grumous fluid; the spleen is enlarged, and there is occasionally peritonitis.

Symptoms. There are epigastric and hypochondriac pain, fever of hectic type, rigors, sweating, vomiting, anæmia and prostration. The portal vein may be sufficiently obstructed to cause some ascites, and the spleen is enlarged. Jaundice is often, but not always present; and if abscesses are numerous, there may be enlargement and pain and tenderness of the liver. The fæces generally contain stercobilin. A typhoid condition supervenes with stupor and delirium, and the disease generally progresses to a fatal termination in from one to seven or eight weeks.

Diagnosis. The disease is easily overlooked. It may be confounded with pyæmia, septicæmia, malarial fevers, acute yellow atrophy, suppurative cholangitis, tropical abscess, subphrenic abscess, typhoid fever, or pneumonia. Local evidence of the liver being involved, and evidence of a local source of infection in the portal area and enlargement of the spleen, point to suppurative pylephlebitis. When local signs are absent, the fact of an obvious pyæmia without external wound, and without endocarditis, might suggest some abdominal organ as the source of the sepsis. Symptoms of septicæmia, marked jaundice and evidence of cholecystitis or gall stones would suggest suppurative cholangitis.

Treatment. The almost necessarily fatal course of the disease renders treatment useless, except as applied to the relief of pain, sleeplessness, and other symptoms.

EXAMINATION OF THE BILIARY APPARATUS

The bile ducts are not merely conducting tubes like the ureters, nor the gall bladder merely a receptacle like the bladder. The bile ducts contain glands which secrete a colourless watery fluid which dilutes the bile, while the gall bladder has the reverse function of concentrating the bile—as much as ten times—to form a thick green fluid. If the hepatic ducts are tied they become distended with the colourless fluid—*white bile*—which collects under such a high tension as to prevent completely the liver from secreting bile into the ducts. If the common duct is obstructed the absorption of water and salts by the gall bladder, amounting in the normal to 90 per cent. of the whole volume, prevents the pressure from rising in the ducts, so that they now contain ordinary bile; but if the gall bladder is cirrhotic or destroyed, the pressure-regulating mechanism is absent and the ducts become filled with white bile, even though every other tissue in the body may be deeply jaundiced. After cholecystectomy, the bile at first leaks continuously into the duodenum, but eventually the ducts may dilate and themselves take on the functions of the gall bladder. (*See also Diseases of the Pancreas.*)

FUNCTIONAL TESTS

Cholecystography. Graham's method depends on the fact that certain dyes opaque to X-rays, after reaching the blood stream, are secreted by the liver into the bile and pass along into the gall bladder. After some hours the bile, and with it the dye, becomes concentrated in the gall bladder (but not in the ducts) so that a radiogram can be taken. The emptying function of the gall bladder may then be tested by giving a fatty meal, when normally the shadow becomes smaller (Plates 31 and 32B).

Tetra-iodo-phenol phthalein, in doses of 3 to 4 grams, according to the size of the subject, is dissolved in 40 c.c. sterile distilled water and injected into the median basilic vein (for precautions, *see* Novarsenobenzol) at 9 p.m., liquorice powder having been given twenty-four hours previously, and a plate of the gall bladder region having been taken. Fatty meals are given during the day, but no food is allowed after 6 p.m. At 9 a.m. the following morning, without food, radiograms are taken and the relation of the shadow to the duodenum determined by a barium meal. At 1 p.m. a fatty meal is taken, and two hours later another X-ray is taken. The injection sometimes causes nausea, vomiting, tingling, and rigor. To avoid this the drug (4.5 gm.) is usually now given by mouth made up into a number of small keratin-coated capsules, but absorption into the blood stream is less certain.

Absence of the gall bladder shadow may be due to blocking of the cystic duct or to the fact that the gall bladder is completely filled with gall stones. A faint shadow may be due to failure to concentrate the dye which suggests cholecystitis. The gall bladder may be shown, and gall stones may also appear in

the gall bladder shadow either as darker shadows from calcium salts or as negative shadows from cholesterin, which is transparent to the rays. The gall bladder shadow may be displaced or distorted owing to neighbouring growths, hydatids, etc.

Duodenal Intubation. Einhorn's duodenal tube provides a valuable method of diagnosing gall bladder disease, though it will not differentiate between cholecystitis and cholelithiasis. After passing the tube into the fasting stomach, which is carefully washed out with sterile water, the patient lies on the left side until the passage of the tube into the duodenum has taken place, as is shown by the fact that on suction through the tube a finely frothing fluid, slightly bile-stained, and neutral or alkaline to litmus is obtained. After washing out the duodenum with sterile distilled water, 10 to 30 c.c. of a 25 to 50 per cent. solution of magnesium sulphate is injected into the duodenum. A copious flow of bile results, which is withdrawn and examined. The presence of cholesterin crystals and leucocytes is suggestive of gall-bladder disease. Cultivation may show the presence of *B. coli*, but this is not so characteristic, as it may be found in any case where the acid of the gastric juice is much diminished.

There is some evidence that certain cases of migraine may be associated with an abnormal emptying of the gall bladder (83)—“bilious migraine.”

DISEASES OF THE BILIARY APPARATUS

CHOLECYSTITIS

The commonest type of cholecystitis is a subacute or chronic infection by streptococci which have been isolated from inside the structure of the walls of the gall bladder (27). It may be a blood borne infection. However, cholecystitis is always accompanied by a pericholangitis, which suggests that the infection may gain access to the gall bladder from the liver *via* the lymphatics. Cholecystitis is commonly associated with appendicitis and peptic ulcer, and it is possible that infection may travel *via* the portal vein to the liver and so to the gall bladder; in other cases there is direct spread through the wall of the gall bladder. Bile inhibits streptococcal growth, and so the bile is usually sterile. An early form of inflammation resulting probably from this type of infection is the so-called *Strawberry Gall Bladder*; small yellowish-white specks are seen projecting from the villi. Microscopically these specks are seen to be cholesterin deposits beneath the surface layer of the mucous membrane, *i.e.* there is a *cholesterosis* of the gall bladder. It has been suggested that normally cholesterol is absorbed from the bile by the gall bladder and that these deposits become formed when the gall bladder wall is infected. Eventually some of these laden papilli are shed into the gall bladder, and so may become the nuclei round which are formed multiple mulberry-shaped calculi; these calculi are sometimes found in this condition. Hence, cholecystitis is the primary cause of gall stones, and the latter have been found at operation in 65 per cent. of cases of cholecystitis. The later results of streptococcal infection are thickening and contraction of the wall of the gall bladder, and adhesions take place to surrounding parts. Apart from the presence of stones an infected gall bladder may cause chronic pancreatitis, cirrhosis of the liver, as well as distant toxic effects on the heart muscle, joints, fasciæ, and kidneys, and lesions have cleared up after the removal of a chronically infected gall bladder (82).

Acute catarrhal or suppurative cholecystitis (*empyema* of the gall bladder) is an obstructive cholecystitis, commonly due to the *Bacillus coli communis*; but *B. typhosis* and occasionally other organisms are found. It may result from impacted stones, typhoid fever, and other infective diseases. In very severe forms the walls are intensely inflamed, œdematous, and infiltrated with pus (*phlegmonous cholecystitis*), and in a still more virulent form they are dark green,

soft, friable, and sloughing in more or less extensive patches (*gangrenous cholecystitis*). The inflammation may of course extend in various directions.

Symptoms. The symptoms of subacute and chronic cholecystitis of streptococcal origin, described above, are commonly insidious in onset. In fact they have been looked on as the inaugural symptoms of gall stones from the fact that the majority of cases of cholecystitis eventually terminate with gall stones. The symptoms are dyspepsia, viz. nausea, heartburn, and epigastric discomfort, and particularly flatulence; there are also aching pains and tenderness on pressure beneath the right costal margin and in the region of the right scapula. The dyspepsia may be similar to duodenal ulcer, but often has not the same striking relation to food. There is commonly pain on pressing the eleventh and twelfth right ribs and the lower dorsal vertebræ. There may also be symptoms corresponding to the complications described above—breathlessness, cardiac irregularities and angina pectoris, and symptoms of rheumatoid arthritis, fibrositis and Bright's disease.

In the case of acute obstructive cholecystitis the onset is acute with persistent or paroxysmal pain in the region of the gall bladder, and great tenderness with rigidity of the upper part of the rectus muscle. Nausea and vomiting, anorexia, a coated tongue, fever, with perhaps rigors, occur, and jaundice in about one-third of the cases. Especially characteristic are signs at the left base, viz. impairment, crepitations, and pleural friction. The right diaphragm is immobile. After a time a definite tumour may be formed by the distended gall bladder. There is leucocytosis in suppurative cases.

Diagnosis. Cholecystitis without the presence of gall stones, not at all an uncommon condition, may be diagnosed when there is severe pain and tenderness beneath the right costal margin and some dyspepsia, and when careful examination has excluded duodenal ulcer and appendicitis. Cholecystography and the "medical" drainage of the gall bladder, as described on p. 403, may be of value in diagnosis.

Prognosis. Milder cases recover with medical treatment.

Treatment. Medical treatment consists mainly in facilitating the emptying of the gall bladder. Medical drainage may be carried out several times a week. The magnesium sulphate may even be given by mouth, but it is not so effective. Fatty meals, and especially olive oil (1 to 2 ounces several times (84) a day) are also of assistance. Inflammation may be allayed by applying poultices and mud packs to the region of the liver and gall bladder. The bile may be disinfected by giving 10 to 20 grains of sodium salicylate three times a day or hexamine (20 grains, increasing to 60 or 80 grains) at night with sufficient alkali, *e.g.* 60 grains of potassium citrate, to make the urine alkaline and to stop irritation of the urinary tract from the hexamine, which decomposes into formalin in acid solution (64). The waters of Harrogate, Vichy and Carlsbad may be specially mentioned. In severe cases cholecystectomy is desirable, and operation will be necessary if there is suppuration.

GALL STONES

(*Cholelithiasis*)

Biliary calculi, or gall stones, are formed from the bile in the gall bladder, or very rarely in the bile ducts in the liver. They vary in size from a mere sand to ovoid masses of 2 inches in length by an inch in breadth; more often they measure from $\frac{1}{4}$ to $\frac{1}{2}$ inch in diameter. They are often roughly cubical in shape, presenting facets when several have been in contact; otherwise they may be more rounded. The largest have the ovoid shape, which would result from their occupying the whole cavity of the gall bladder. The chief constituents of gall stones are cholesterin, bile pigment, protein and calcium salts; and the bile pigment is mostly combined with calcium, as bilirubin-calcium. Those which consist mainly

of bile pigment are small, dark and friable. Others have a nucleus or centre of bile pigment, and are surrounded by layers of cholesterin crystals which radiate from the nucleus; these stones are generally larger, harder, and have a paler colour. Soft stones consisting mainly of calcium carbonate are found when the cystic duct is obstructed. The hard greenish calcium carbonate stone contains copper.

Ætiology. Gall stones are commoner in advanced life, and occur in women more often than in men. Sedentary occupations and over-indulgence in food, especially cholesterin-containing foods, are predisposing causes, and possibly pregnancy and typhoid fever.

Pathology. The view that a cholecystitis is the primary cause of gall stones has already been described. Given some foreign material to act as a nucleus the formation of gall stones has been proved to occur even though the bile remains sterile. They have been found in 10 per cent. of autopsies, and may remain latent (81), though their presence may aggravate the cholecystitis. However, in consequence of irritation in the gall bladder, due to inflammation, one or more stones may be forced out of the cavity and may pass down or be impacted in the cystic duct. The immediate effect is extremely painful spasm of the duct (*biliary colic*), but without jaundice. In the case of impaction bile is unable to enter the gall bladder, which becomes distended with mucus, or muco-pus, or pus. If the cystic duct is traversed the stone enters the common duct, and gives rise here also to biliary colic, accompanied, however, by transient jaundice, owing to the resistance offered by the presence of the stone to the outflow of bile from the liver. If the stone is impacted in the duct, obstructive jaundice results. The impaction commonly occurs at the ampulla of Vater, where the diameter of the duct is smallest. This continued obstruction has the following effects:—

(α) The liver is at first considerably enlarged from dilatation of its ducts, which are distended with bile. Sometimes the ducts are dilated uniformly, at others more irregularly into globular cysts. They exert a certain amount of pressure on the tissue of the liver, and cause it to atrophy, so that subsequently the liver becomes smaller and rather flaccid. Suppurative cholangitis may supervene.

(β) The effect of the impaction on the gall bladder might be expected to cause its distension; but this usually does not occur unless the gall bladder is simultaneously acutely inflamed, because chronic inflammation leads to fibrosis and shrinking up of the gall bladder.

(γ) When a gall stone is fixed in the ampulla of Vater, the relations of the pancreatic duct, which opens here, are of importance, since it will also probably be blocked with a retention of pancreatic juice. Micro-organisms will readily pass through the walls of the bile duct into the pancreas, and with the retained secretions set up acute or chronic pancreatitis (*q.v.*).

It is not a very uncommon event for a gall stone to ulcerate through the wall of the gall bladder directly into the duodenum or into the transverse colon; generally it is a large gall stone, an inch or more in diameter, which, if it enters the duodenum, may become impacted in the lower part of the ileum, or, if it enters the colon, may be passed *per anum* after more or less pain and difficulty from obstruction at the sigmoid or near the anus. Rarely a large stone has been vomited.

Another result of the presence and persistence of gall stones in the gall bladder is *carcinoma* of the gall bladder or bile ducts, and this has been found in about 5 per cent. of cases of cholelithiasis. Experimentally, it has been shown that the introduction of gall stones and other foreign bodies into the gall bladders of guinea pigs causes carcinoma from the chronic irritation (85).

Symptoms. Gall stones may remain in the gall bladder for years without giving rise to any symptoms. But in other cases the symptoms are those of subacute and chronic cholecystitis, and the dyspepsia of the co-existing cholecystitis is commonly called *gall stone dyspepsia*. The gall stones can sometimes be felt through the abdominal wall and give a sensation of crackling on being

handled. In an attack of biliary colic the patient is seized, often suddenly, with agonising pain in the right hypochondrium and lower part of the chest, or in the epigastrium and lower sternum; and it commonly radiates to the right shoulder. The pain is often so severe that he is bent double, or writhes on the floor or bed. Rigors may occur, and the patient is pale, collapsed, with profuse sweating and a small, feeble, generally quick pulse. After a time the pain becomes dull and aching, until a fresh attack of the acuter kind occurs; or the pain persists, and within a few hours or a day or two of the beginning of the pain bile pigment appears in the urine, and the patient becomes jaundiced. This may end by the passage of the stone into the duodenum, when the bile again flows freely, the pain subsides, and more gradually the jaundice clears up. When this happens, the fæces should be searched for the gall stone, which may be found by washing them with water and passing the washings through a sieve. When the stone is impacted in the common duct the symptoms are variable, but the most typical "Charcot" syndrome is recurring colic, rigors, jaundice and loss of weight. Since gall stones are usually associated with cholecystitis (*q.v.*) the corresponding symptoms may also be present.

Diagnosis. Biliary colic may be confounded with gastric pain, intestinal colic, renal colic, etc. But the passage of gall stones is not always associated with pain, and cases of impaction with jaundice may be misunderstood from the absence of this symptom. In cases of jaundice due to obstruction of the common duct, if the gall bladder cannot be felt, the obstruction is due to gall stones; if there is a lump, the obstruction is probably due to some other cause, usually a growth (Courvoisier's law). This is correct in about 90 per cent. of cases in practice. Gall stones differ considerably in the extent to which they intercept the X-rays, and thus reveal themselves by their shadows. Pure cholesterin gall stones are transparent to X-rays and give a "negative" shadow, *i.e.* a clear area in a cholecystogram (Plate 32, B). The bilirubin and calcium salts, when present, obstruct the rays (Plate 31). A very characteristic appearance is a rounded opacity with an opaque centre and a clearer layer surrounding it. Duodenal intubation should also be used.

Prognosis. This need not be unfavourable in a first attack of colic; many people recover even after several; but the possible onset of carcinoma must not be forgotten.

Treatment. The treatment of cholecystitis should be consulted.

For an attack of biliary colic the patient should be placed in a hot bath, or hot fomentations or poultices should be applied to the right side. Most relief will be obtained from the subcutaneous injection of $\frac{1}{4}$ to $\frac{1}{2}$ grain of morphia, repeated, if necessary, in three or four hours. Sometimes chloroform may be inhaled with temporary relief. Papaverine hydrochloride ($\frac{1}{2}$ to $1\frac{1}{2}$ grain) by mouth may also be tried.

When the gall stones are a constant source of trouble, or if complications are feared, cholecystotomy should be performed, and the stone or stones can be removed from the bladder or ducts. It may be advisable to remove the gall bladder.

SUPPURATIVE CHOLANGITIS

This is always due to infection by micro-organisms, *e.g.* streptococci, staphylococci, pneumococci, the typhoid bacillus, and *Bacillus coli communis*; and is either determined by local diseases, such as gall stones, the most common cause, by carcinoma, by hydatid cyst rupturing into the ducts, or by the more general infections of influenza, pneumonia, typhoid, and cholera. There is swelling and thickening of the bile ducts throughout the liver; the organ becomes enlarged; the ducts are dilated, and numerous foci of suppuration, forming smaller or larger abscesses, occur. The inflammation may extend to the pancreatic duct, and cause suppurative pancreatitis; or abscesses near the surface

may lead to localised or general peritonitis. Occasionally infection extends so as to cause a general pyæmia or infective endocarditis.

The **Symptoms** are pain and tenderness over the liver, loss of appetite, nausea, vomiting, rigors, pyrexia, which may be intermittent resembling malaria, prostration, and often jaundice. The condition is sometimes called *intermittent hepatic fever*. The liver usually increases in size as the illness progresses. The spleen may be enlarged. The duration is from a few weeks to some months, and the disease is fatal.

Diagnosis. See Suppurative Pylephlebitis.

Treatment. This can only be surgical. The bile ducts must be drained, where possible, by opening the gall bladder, or any ducts which may be accessible.

EXAMINATION OF THE PANCREAS

The pancreas contains two different types of secreting cells: (1) *acinar* cells, which secrete the pancreatic juice; (2) cells of the *islands of Langerhans*, which secrete a hormone necessary for the metabolism of carbohydrate. These cells may be affected by disease independently of one another.

Recent observations have shown the following relation between bile and pancreatic juice during healthy digestion. During the period of alimentary rest the liver continuously secretes bile which is stored in the gall bladder. After eating, peristaltic waves of contraction pass down the intestine from the pyloric sphincter of the stomach. Each wave is preceded by a negative wave of relaxation, so that some bile escapes through the relaxed sphincter of Oddi. This bile is mixed with the contents from the stomach, which gives it an adequate reaction to ensure the absorption of bile-salts through the intestinal mucosa. The bile-salts in their passage through the cells adsorb the preformed secretin contained in them and pass into the portal blood. The secretin causes the pancreas to secrete and the liberated bile-salt is carried to the liver to cause the secretion of a further quantity of bile. In addition the secretin in the portal blood causes the gall bladder to pass into a state of sustained contraction, so that more bile passes into the duodenum. The pancreatic secretion called forth by secretin is a dilute solution of sodium bicarbonate of the correct pH which washes out the preformed ferments. For the production of ferments varied stimulation is required. The activation of trypsinogen in the duodenum is caused by enterokinase, leucocytes, bacteria, etc. (86).

FUNCTIONAL TESTS OF THE PANCREAS

Most of the functional tests of the pancreas consist in determining whether there is a deficiency (a) in the external secretion from the acinar cells, (b) in the internal secretion from the islands. However, Loewi's *mydriatic test*, which is only positive in a proportion of cases, and is also positive in some cases of exophthalmic goitre, depends on some functional connection of the pancreas with the sympathetic system. The eyes are examined to see whether the pupils are equal and react normally. Into one of them a solution of adrenin (1 in 1,000) is dropped and the eye closed. This is repeated twice during five minutes. The eyes are not used for an hour. If during this time the pupil of the adrenalised eye is larger than that of the other eye, which is used as a control, the test is positive and indicates pancreatic disease.

Deficiency of External Secretion. *Steatorrhœa* has up to the present been regarded as one of the most characteristic signs of pancreatic disease. It consists in the passage of liquid fat in the stools, which solidifies on cooling, forming white or yellow lumps. The stools are bulky, soft and pale, and besides unaltered fat they may contain fatty acids and soaps. Where the stools are not obviously altered to the naked eye the microscope may reveal numerous fat globules and fatty acid crystals. In estimating the degree of *steatorrhœa*

chemically, it is important to determine not only the fat in the stools, but also to know the fat taken in the diet. In severe cases from 50 to 60 per cent. of the fat intake is lost in the stools. The normal loss is only about 10 per cent. and not more than $\frac{1}{4}$ – $\frac{1}{3}$ of the dried faeces is fat, and of this not more than $\frac{1}{4}$ – $\frac{1}{3}$ is split into glycerine and fatty acid.

There are two reasons for doubting that steatorrhœa is usually pancreatic in origin: (1) because it very commonly arises from defective absorption where the lacteals are obstructed from abdominal tuberculosis or growth. In these cases the fat in the stools is largely split. (2) Evidence is forthcoming that the presence of bile in the intestine is a much more important factor in fat absorption than the pancreatic juice. In fact, experimental ligature or extirpation of the pancreatic ducts do not seem to affect the absorption (74). Congenital steatorrhœa has been described, and in diarrhœa, cœliac disease and gastrocolic fistula the fat in the stools is increased, and the stools are bulky.

Creatorrhœa is due to the absence of trypsin. Large numbers of undigested striped muscle fibres, derived from the meat eaten, are observed microscopically in the stools. Creatorrhœa also occurs in profuse diarrhœa, so that to avoid this fallacy charcoal is taken with a meat meal, and the black stools are examined only if they have been passed between eighteen to thirty hours after ingestion (87).

Diastase in the Urine. The test is carried out on a twenty-four hours' specimen. To get accurate results it is essential first of all to titrate the urine with

$\frac{N}{10}$ NaOH or HCl until the acidity is optimum, i.e. the pH of the urine is 6·7. This is the case when after the addition of phenol red as an indicator the urine shows a faint pink tinge (92). 0·6, 0·4, 0·2, and 0·1 c.c. of the urine are put in four tubes and normal saline (0·9 per cent.) added, so as to make 1 c.c. in each case. The same procedure is adopted after the urine has been diluted ten times with normal saline, so that the eight tubes contain strengths of urine corresponding to 0·6, 0·4, 0·2, 0·1, 0·06, 0·04, 0·02, 0·01. To each tube are added 2 c.c. of 0·1 per cent. soluble starch. The tubes are incubated

for half an hour at 39° C. After cooling, $\frac{N}{50}$ iodine is added drop by drop to the tubes in series, starting from the tube containing 0·01 strength of urine, until there ceases to be a change of colour. The first tube in which the blue colour ceases to be developed gives the amount of diastase in the urine, which is reckoned by dividing 2 by the strength of the tube. If, for example, the blue colour is not found in the 0·06 tube, the amount of diastase would be 33 units. The normal amount of diastase varies between 10 and 40. In pancreatic disease the amount of diastase in the urine (i.e. the diastase index) is increased. It is possible that this test is really concerned with the *internal* secretion of the pancreas. Cammidge believes that a deficiency of this leads to liberation of hepatic diastase into the blood and its increase in the urine.

Deficiency of Internal Secretion. In a marked case this leads to glycosuria, and in less marked cases there may be a decrease in *sugar tolerance*. This is best tested by giving a patient a dose of dextrose and observing the rise in the blood sugar, as well as whether any sugar is excreted in the urine (see p. 463). The work of Cammidge, Forsyth and Howard is of very great theoretical interest, and may lead to valuable means of detecting a deficiency of the internal secretion of the pancreas in its earliest stages. They consider that the liver contains an amylolytic ferment which breaks down glycogen through a stage of dextrin-like bodies into dextrose. The activity of this ferment is normally kept in check by the internal secretion of the pancreas. If the latter is deficient, there is first of all an excess of these dextrans in the blood and in the urine, into which they are excreted, while the blood sugar remains at about its normal level. In a later stage these dextrans are broken down completely into dextrose, so that there

is now hyperglycæmia and glycosuria, while the dextrins disappear from the blood and urine. This latter is the condition found in diabetes mellitus. The amount of dextrins in the blood was measured by hydrolysing them with hydrochloric acid so that they were converted into dextrose. The total dextrose was then estimated. The "difference value" between this quantity and the amount of dextrose present in the original blood before hydrolysis gives the amount of dextrose which was due to the dextrins. The same method may be used for the urine, or a direct method involving the use of iodine can be employed. These determinations take the place of the original Cammidge's reaction, which is not reliable.

DISEASES OF THE PANCREAS

ACUTE PANCREATITIS

Pathology. Experiments and clinical observations show that acute pancreatitis is in the majority of cases due primarily to bacterial infection, which activates the pancreatic juice by converting the trypsinogen into trypsin. The characteristic appearances of the diseased gland are due to its digestion by the active pancreatic juice. Acute pancreatitis is predisposed to by obesity, and the attacks may be recurrent, ending in one final catastrophe. It is commonly associated with gall stones or cholecystitis; but it is not very common in acute pancreatitis for a gall stone to be found impacted in the ampulla of Vater, and when this is the case the stone is probably large enough to block the exit of Wirsung's duct, and so prevent bile from passing up it into the pancreas. However, it is possible that small stones cause intermittent stasis in the pancreatic duct by impaction at the ampulla, and the associated infection spreading from the bile ducts starts the attack. It is quite common for a history of repeated mild attacks of biliary colic to be obtained, which would fit in with this hypothesis. Acute pancreatitis may start from other neighbouring foci of infection, such as duodenal ulcer and cholangitis, and it sometimes occurs in infective diseases, such as enteric fever, pyæmia, and septicæmia, and also in mumps, which is of interest from the structural resemblance of the pancreas to the salivary glands.

In *acute hæmorrhagic pancreatitis* the organ is swollen, friable, and mottled red or brown to black, with hæmorrhages on the surface and in the interstitial tissue; and the blood may extravasate in the surrounding structures, or there may be blood-stained fluid in the peritoneal cavity. Microscopically the parenchymatous tissue is found to be necrosed, and there is usually associated inflammation, as shown by infiltration with polymorphonuclear cells. This is probably secondary to the digestion by pancreatic juice. *Fat necrosis* is always a prominent feature. In the pancreas, and in the subperitoneal fat adjacent, sometimes in the perinephric, mediastinal, and pericardial fat and even in the subcutaneous fat, are small masses of dull yellow or opaque white colour, sharply differentiated from the adjacent healthy fat, and sometimes surrounded by a narrow hæmorrhagic zone. They are produced by the action of the fat-splitting ferment (*lipase*) of the escaped pancreatic secretion upon the fat; the liberated fatty acids combine with calcium base, while the glycerine is absorbed.

At a later stage, or if the process is more chronic, *suppurative pancreatitis* occurs. The organ is large, swollen and infiltrated with pus; or it contains separate abscesses. An abscess may burst into the peritoneal cavity, or into the stomach or bowel; thrombosis and infection of the portal and splenic veins may also occur with metastatic abscesses in the liver. The *Bacillus coli communis* and pyogenic organisms are found in different cases. In both forms death may follow from acute peritonitis.

Symptoms. When pancreatitis occurs in the course of mumps, there

are vomiting and epigastric pain, with swelling and tenderness in the epigastric region. The more intense *hæmorrhagic pancreatitis* is characterised by severe, even excruciating, pain in the upper part of the abdomen, radiating through to the back; it is worse than the pain of perforated peptic ulcer, and is often unrelieved by morphia. However, there is usually not very much rigidity, since owing to the antiseptic nature of the fluid there is usually no general peritonitis. Shock, accompanied by cyanosis, comes on early, possibly owing to the absorption of proteolytic substances. The symptoms often come on quite suddenly in the midst of apparent health. Occasionally, after a few hours, a circumscribed, tender swelling appears in the upper part of the abdomen, but the difficulties of diagnosis are such that the abdomen has often been opened for the relief of a supposed intestinal obstruction. The cases are generally fatal within four or five days, but some have recovered after laparotomy. The symptoms of *suppurative pancreatitis* are similar, but less pronounced and acute, and the case may last several months. A tumour is only felt in one quarter of the cases, and this is due to accumulation of fluid in the lesser peritoneal sac. Symptoms referable to failing pancreatic functions have not very often been reported, but this is probably because they have not often been looked for. Glycosuria and an increase in the urinary diastase would be a valuable help in diagnosis. Jaundice is sometimes present.

Treatment. Laparotomy should be immediately performed if the symptoms are urgent. The condition that is found may suggest local measures. Thus with a hæmorrhagic lesion the organ has been incised, the hæmorrhage checked by ligature, and drainage instituted with success. In a case of suppurative pancreatitis, incision of the abscess and drainage are absolutely necessary. In any operation the gall bladder and common bile duct should be examined for cholecystitis and gall stones and the gall bladder drained.

CHRONIC PANCREATITIS

This affects the interstitial tissue, producing considerable fibrous growth, with consequent atrophy of the glandular structures, analogous to the changes in cirrhosis of the liver; and, as in that disease, the fibrous network may enclose large groups of acini (*interlobular*), or much more rarely single acini (*interacinar*). The head of the organ is usually most affected. The substance is rendered extremely dense and hard, and in the less frequent *interacinar* form considerable enlargement may take place. The ætiology of chronic pancreatitis is much the same as that of acute pancreatitis. It commonly arises from the spread of adjacent inflammations, such as those of the peritoneum, of the bile duct, of the stomach and of the intestines, such as appendicitis, by which infective organisms may be conveyed up the pancreatic duct. It also results from the presence of concretions in the pancreatic duct, or of retained pancreatic secretions; from compression of the duct by cancer; from the venous congestion of heart disease; and possibly from syphilis, and the abuse of alcohol. Gall stones are a common cause of chronic pancreatitis, especially when one lies in the ampulla of Vater, or in the common duct, or when there is suppurative cholangitis, the result of their presence. In most of these instances of duct obstruction and infection it is the *interlobular* form which is caused. Arterio-sclerosis is also a cause of chronic pancreatitis, which is then commonly of the *interacinar* variety.

Morbid Anatomy. In the *interlobular* form the pancreas is dense and hard, with broad bands of fibrous tissue running between the lobules and embedded areas, some of disintegrating glandular substance, some of well-preserved tissue. As a rule the islands of Langerhans are untouched. In the *interacinar* form the acini are separated from one another by coarse strands of fibrous tissue, the acini are atrophied, and the islands of Langerhans are frequently involved in lymphoid-cell infiltration and sclerosis.

Either form of chronic pancreatitis may be complicated by a large deposit of fat, *lipomatosis*, especially in persons the subjects of obesity.

Symptoms. A case of the writer's was a man aged 49 who had symptoms exactly simulating duodenal ulcer, with a small transverse stomach, emptying rapidly, but no deformity of the cap and no occult blood. Operation was carried out for suspected gall stones, but the biliary tract, etc. were normal. Other cases have no symptoms, or ill-defined dyspeptic symptoms, or there may be emaciation with well-marked pancreatic deficiency. Again, the swollen head of the pancreas may compress the common bile duct which it surrounds, and thus cause obstructive jaundice, which often leads to operation, when a hard pancreas is felt; in about one-third of the cases the lump is due to pancreatitis, and in two-thirds to carcinoma of the head of the pancreas.

Where diabetes mellitus results from chronic pancreatitis, Opie states that it results almost entirely from the interacinar form, in which especially the islands of Langerhans are injured, and from the interlobular form only in extreme instances when the islands, situated in the centres of the lobules, are reached by the degenerative process.

Treatment. As the chronic inflammation is attributable in so many cases to disordered conditions of the biliary and pancreatic ducts, and of the gastro-intestinal mucous membrane, the treatment of these primary disorders is the first consideration. The former will often require operation for the removal of calculi, and the latter will need suitable dietetic and medicinal treatment. Cases have been reported where prolonged drainage through the gall bladder has been successful in relieving symptoms.

PANCREATIC CALCULI

These may occur in middle-aged men; they are by no means common. They are attributable to catarrh of the ducts with delayed secretion, and consist of calcium carbonate and calcium phosphate, and sometimes calcium oxalate. They may be like grains of sand, or as large as hazel-nuts, and are usually round or oval, occasionally irregular or branched. In colour they are white or greyish white, sometimes brown or nearly black. They sometimes block the duct or its branches, and lead to dilatation of the ducts, retention cysts, acute inflammation with suppuration or chronic induration, and even to inflammation in the parts around. They rarely produce symptoms, except through their secondary effects—for instance, by the inflammation which they excite, or by the formation of cysts, or by the production of atrophy and cirrhosis of the gland.

Diagnosis is made by means of radiography and by examination of the stools for calculi. They have occasionally been removed successfully by operation, in most cases from the duct of Wirsung.

NEOPLASMS OF THE PANCREAS AND CYSTS

Carcinoma, which is nearly always primary, is the most important tumour of the pancreas. It is often confined to the head of the gland. It is an irregular nodular hard tumour, which may be of sufficient size to be felt under favourable circumstances through the abdominal parietes. As the nodules increase in size the pancreatic duct is liable to be obstructed, with the formation of a cyst as a result; and the common bile duct is not infrequently blocked either by pressure or by the spread of a chronic inflammation, so that jaundice is produced. This is, indeed, a common cause of jaundice in persons of middle and advanced age. In other instances the carcinoma may involve the stomach, duodenum, peritoneum, vertebræ, or other structures. The symptoms resemble those of chronic pancreatitis; but emaciation becomes usually marked.

Pancreatic Cysts. These develop more frequently in the tail and body of the gland; they may be retention cysts from obstruction of the duct of Wirsung by

calculus or by pressure from without. Others are formed in the substance of the gland as the after result of a hæmorrhagic pancreatitis. Pseudo-cysts develop in the neighbouring peritoneum, and are due to the out-pouring of fluid to dilute the irritating pancreatic juice which is liberated as the result of acute pancreatitis.

A cyst of sufficient size forms a globular tumour in the upper part of the abdomen, either in the median line or to one side of it; it may project below the transverse colon, resembling an ovarian cyst, though it may be pushed upwards on palpation from below; it may project forwards between the stomach and transverse colon or between the liver and stomach. Its relations can be determined by X-ray after an opaque meal or by percussion after insufflation of the hollow viscera. A pancreatic tumour is often stationary during deep inspiration, but if in contact with the diaphragm, it may move downwards $\frac{1}{2}$ or $\frac{3}{4}$ inch. The fluid within it is turbid, brown or greenish in colour, alkaline, albuminous and of specific gravity 1,010 to 1,020; it may contain altered blood pigment and the various pancreatic ferments. There is emaciation and sometimes pain or jaundice. The urine sometimes contains sugar.

The swellings most likely to be confounded with it are a hydatid cyst of some other organ, hydronephrosis, circumscribed peritonitis, and ovarian disease; if much to the left and moving on inspiration it may resemble a splenic or renal tumour. The nature of the aspirated fluid should help. Congenital cysts and hydatid cysts of the pancreas occur rarely.

Treatment. Pancreatic cysts have often been successfully treated by incision and drainage. Other tumours are less easily dealt with, and treatment must be directed to the relief of symptoms. If the tumour cannot be removed, some relief may be obtained by cholecystotomy or cholecyst-enterostomy.

DISEASES OF THE PERITONEUM

ACUTE PERITONITIS

Ætiology. Acute peritonitis may be due to a blood-borne infection, *i.e.* pneumococcal peritonitis, and very rarely streptococcal peritonitis. The most frequent cause is some lesion of the abdominal viscera, such as perforated peptic ulcer, perforated typhoid and tuberculous ulcers of the ileum, and dysenteric ulcers of the colon, inflammation and sloughing of the appendix cæci, abscess of the liver, suppuration of the gall bladder, acute intestinal obstruction with strangulation, infarction and abscess of the spleen, the numerous inflammatory lesions which are apt to involve the female pelvic organs—metritis, parametritis, ovaritis, salpingitis, and pelvic hæmatocele, and sometimes infection spreading from a pyelonephritis, perinephritis, psoas abscess, acute pleurisy or empyema; but empyema is much less commonly a cause of peritonitis than a peritoneal abscess is a cause of empyema.

In many of these cases the peritonitis is set up by the discharge into the abdominal cavity of liquids, such as food, fæces, or pus, carrying with them infective micro-organisms; this happens in the case of the perforation of gastric and intestinal ulcers, in appendicitis, and in rupture of abscesses. In other cases there is an extension of inflammation to the serous layer; that is, the micro-organisms penetrate the tissues without coarse rupture. Wounds of the peritoneum, whether from injury or surgical procedure, are liable to be followed by peritonitis. Bright's disease, whether acute or chronic, is an occasional predisposing cause of peritonitis.

Bacteriology. The micro-organisms causing peritonitis are usually the *Bacillus coli communis* when the peritoneum is infected from the intestine, as in appendicitis or perforation of the bowels, or from the biliary passages; streptococci and staphylococci are found in peritonitis derived from lesions of the pelvic organs, or the abdominal walls. The pneumococcus is also met with; the

peritonitis may be primary or it may be associated with pneumonia, or it may be part of a pneumococcal septicæmia. Other bacteria less frequently found are *B. typhosus*, *B. pyocyaneus*, *B. lactis aerogenes*, *Micrococcus tetragenus*, and the gonococcus. The amœba coli has been found in amœbic dysentery; the tubercle bacillus occasionally causes acute inflammation, but much more commonly a chronic form.

Morbid Anatomy. The changes which take place in the peritoneum are not unlike those which occur in the pleura when it is inflamed. There is at first redness from increased vascularity, and if the cavity of the abdomen is examined in this early stage, the redness of the intestines is commonly seen to form parallel streaks along the intestine in the position where three peritoneal surfaces meet, *i.e.* two coils of intestine and the anterior abdominal wall or three coils of intestine. The pressure is lower at this position than elsewhere, so that congestion and exudation occur first here, forming a space along the gut which is triangular in section. The exudation coagulates, producing a yellow flaky deposit, which is often loosely spoken of as *lymph*, but which consists of fibrin and leucocytes, and there may be present a varying amount of turbid fluid in addition. The exudation appears with great rapidity, as may be seen in some traumatic cases, where a quantity of yellow lymph may be formed in less than eighteen hours. In some less severe or less extensive cases, the exudation may be replaced by fibrous tissue (*organisation*); and the different viscera are united together, or the peritoneal cavity is obliterated, by the adhesions which are thus formed. In other cases, the quantity of leucocytes increases, or is more numerous from the first, and the inflammatory products are entirely purulent; this is often quickly fatal.

Acute circumscribed peritonitis or *peritoneal abscess* results from the localisation of the infection. The *appendix abscess* is the commonest type of peritoneal abscess. Peritoneal abscesses occur in the pelvis, in the lumbar regions, iliac fossæ, or beneath the diaphragm—subphrenic abscess, which is considered later. They may point externally or open into one of the hollow viscera, or they may rupture into the chest and set up pleurisy or pneumonia. A peritoneal abscess not infrequently contains air from direct communication with the stomach or intestines by perforation of an ulcer.

Symptoms. *Acute general peritonitis* begins with pain, which is mostly very severe, and, if at first localised to one spot, soon becomes diffused over the whole abdomen. The pain is constant, but aggravated by every kind of movement, by coughing, straining, or vomiting. It is not relieved by pressure; on the contrary, there is marked tenderness over the whole of the abdomen. There is immobility of the whole abdomen on respiration, which is entirely thoracic, and a rigidity on palpation which is never relaxed—a very important sign. The legs are frequently drawn up to prevent stretching of the abdominal parietes, and every movement is avoided by the patient. The pulse is generally quickened, and the temperature is raised; but sometimes the temperature is low, though the pulse is rapid, and this is to be regarded as a sign of severe infection, as the pulse rate is a more important indication of severity than the degree of temperature. Vomiting, as a rule, soon sets in, and occurs repeatedly, either spontaneously or after attempts to take food. At first the gastric contents are brought up, subsequently bile, and later still the vomit is almost feculent in character. Sometimes also rigors occur at the commencement, but there is always a considerable degree of collapse. In the later stages the patient lies on his back, with shrunken face, dark sunken eyes, anxious expression, dry furred tongue, and quick small pulse. The abdomen becomes swollen from paralysis of the muscular coat of the intestines and the accumulation of gas within them. The surface is resonant, but if much fluid is poured out, it may cause dulness at the flanks, or occasionally all over. Hiccough is a frequent symptom. Constipation is the rule, but sometimes, after two or three days, one or more

motions may be passed, or even diarrhœa may set in ; and occasionally there is diarrhœa from the first. The urine is scanty ; it may be passed with pain, or be retained.

In cases of perforated peptic ulcer there is at the beginning generalised abdominal rigidity and shock, with livid, anxious face, cold, damp extremities, sub-normal temperature, rapid, weak pulse. The later signs of acute peritonitis eventually appear. Gas may escape into the peritoneal cavity and cause extensive resonance or even splashing from mixture with the liquid. The extravasation of gas into the peritoneum is sometimes recognised by its lying in front of the liver and replacing the natural hepatic dulness by resonance. But it must be remembered that the liver may be displaced from its contact with the anterior thoracic wall by much gaseous distension of the viscera, without any escape of gas from their interior.

The patient gradually gets exhausted by vomiting and pain, the tongue becomes drier and brown, sordes form on the lips and teeth, the pulse is smaller and quicker, the bases of the lungs are compressed, and after an illness of from two to six days death takes place. It is not, however, every case that presents all the characteristic signs. Fever is absent in some cases ; there is but little distension in others ; occasionally a patient, instead of lying prostrate on his back, will throw himself about in the agony of pain.

In *pneumococcal peritonitis*, which usually arises as part of a pneumococcal septicæmia, there is pain and tenderness of the abdomen, and diarrhœa. There may be rigidity, but more often the wall is flaccid. The toxic symptoms are pronounced, with high temperature and delirium, and the respiration rate is raised, and there may be herpes labialis or evidence of pneumococcal infection elsewhere, in the lungs, joints, etc. After a time an abscess forms in one part of the abdomen, and this is indicated by the appearance of a swelling in the particular region.

In *acute circumscribed peritonitis* the general symptoms are much the same, but the local conditions are more or less limited to the region affected. The commonest cause is appendicitis with perforation, and this has already been described.

Diagnosis. As a rule, this is not difficult : the severe pain, tenderness, vomiting, rigidity, and immobility of the abdomen during respiration, followed by distension, constipation, small quick pulse, and collapse, form the important features. But peritonitis may be simulated by the severe pain of colic, by ruptured aneurysm, mesenteric thrombosis, and by acute hæmorrhagic pancreatitis ; it may itself be mistaken for intestinal obstruction ; and it may be set up, and cause death without its presence being suspected, in enteric fever, and after operations on the abdominal walls, such as herniotomy. *Colic* and *hysterical pain* are mostly to be distinguished from peritonitis by the contracted abdomen and the absence of tenderness, indeed, the relief on pressure, in the former case, and the extreme sensitiveness to the merest touch, without pressure, in the latter. *Rupture* of an *ectopic gestation* causes pain and collapse, and may be mistaken for the perforation of a gastric ulcer. There may be a history of vomiting, and menstrual irregularity ; owing to profuse hæmorrhage there is blanching of the lips ; there is tenderness and swelling of the abdomen, and sometimes free fluid, but no true rigidity, and pelvic and rectal examination discloses a tense lump. A valuable means of confirming a diagnosis of *perforated peptic ulcer* is in use at Lewisham Hospital. An X-ray film in the vertical position by a clear area between the liver and right diaphragm in the peritoneal cavity indicates the presence of free gas (see Plate 32, A). Perforative peritonitis is sometimes simulated by the fatal coma of *diabetes*. This occasionally begins suddenly, with severe abdominal pain and small, thready pulse. The air hunger of diabetes and the presence of much aceto-acetic acid in the urine and absence of abdominal rigidity should clear up the diagnosis.

As to the differential diagnosis of peritonitis, its cause must be looked for in the preceding history. Where severe acute peritonitis ensues in a person previously considered well, ulceration of the appendix cæci, perforated gastric ulcer, and lesions of the pelvic organs are the most likely causes. The first is more probable in both sexes before and about the age of puberty; the last occurs almost exclusively in females, and in girls the possibility of a neglected vulvovaginitis causing gonococcal peritonitis should be thought of. The characteristics of a primary pneumococcal peritonitis, which occurs chiefly in children, have already been described.

Prognosis. General peritonitis is a very fatal disease. The probable result must be estimated by the character of the pulse, the persistence of vomiting, the amount of collapse, and the probable extent of the inflammation. Severer cases can only be judged of from day to day. There is more hope when some days have elapsed, but in cases that are apparently improving accumulations of pus may reveal themselves, and become dangerous in the way indicated. Pneumococcal and gonococcal forms are relatively favourable.

Treatment. The majority of cases of peritonitis, and especially those due to perforation of a gastric, duodenal, or typhoid ulcer, or sloughing of the appendix cæci, or other similar accident, are only likely to recover if promptly treated by surgical methods: the abdomen must be opened, and the causative lesion dealt with, and collections of pus must be drained. In peritonitis having its origin in a septicæmia, *e.g.* pneumococcal peritonitis, an operation should not be carried out unless an abscess has formed, since it will not be possible to remove the primary focus.

Supposing it has been decided not to operate, the first principle of treatment is to keep the intestines completely at rest. For this purpose the patient must, of course, be in bed; food may be given by means of rectal enemas containing 6 per cent. dextrose; and purgatives should be strictly avoided. The patient's thirst may be quenched by small pieces of ice sucked from time to time, but no food should be allowed by the mouth. Opium or morphia should not be used, as their administration may mark an increase in the symptoms which might render operation necessary. Relief is afforded locally by the application of hot linseed-meal poultices, or flannels wrung out of hot water and sprinkled with turpentine or liniment of belladonna. Ice compresses or pieces of ice between layers of flannel are sometimes used, but they do not generally give so much relief as the hot applications. Stimulants are often required, and are best given in the form of brandy, in small quantities frequently. When there is distension, anti-Welch serum may be injected (*see p.* 380).

Subphrenic Abscess may occur in the peritoneum or in the cellular tissue beneath the diaphragm. The most frequent positions are classified as follows: (1) the right anterior intra-peritoneal abscess is above the right lobe of the liver and to the right of the falciform ligament; the pus often spreads beneath the liver posteriorly. The commonest causes are appendicitis, perforated duodenal ulcer and hepatic abscesses. (2) The left anterior intra-peritoneal abscess, due principally to perforated gastric ulcer, is situated above the left lobe of the liver and around the spleen. (3) The right extra-peritoneal abscess is situated in the cellular tissue above and behind the liver, and originates from inflammation in the liver, right retro-peritoneal tissues and the thorax. There is little subphrenic cellular tissue on the left side, so that inflammation here tends to produce a lumbar abscess. Suppuration in the lesser peritoneal sac, which arises from perforated gastric ulcer, is not so common as in the other situations mentioned (91). Pain is the earliest symptom of subphrenic abscess. Besides the general symptoms of a febrile disturbance due to suppuration, there are important localising signs, *viz.* an abdominal swelling which does not descend on inspiration, bulging of the thoracic walls on the side of the abscess, with deep tenderness. At the base of the corresponding

lung there are dulness and diminution of breath sounds, vocal resonance and tactile vocal fremitus. X-ray examination shows that the corresponding diaphragm is raised and immobile. When the abscess contains air, as may happen if it results from perforation of a viscus, a pneumothorax is simulated by the occurrence of tympanitic note, amphoric breathing, metallic tinkling, and bell sound. Exploratory puncture is best carried out under an anæsthetic, and if positive the cavity should be drained by open operation.

CHRONIC PERITONITIS

This may arise as a sequel of acute peritonitis, especially in its local forms; it is often the result of local irritation about particular organs—for instance, the liver or the spleen may be surrounded with a thickened capsule (perihepatitis, perisplenitis). The growth of tubercle and carcinoma in the abdominal cavity gives rise to forms of chronic peritonitis which will be spoken of shortly. It may occur in Bright's disease.

Adhesions and Bands between the viscera may be another form of chronic peritonitis resulting from acute or chronic inflammation, and leading occasionally to acute intestinal obstruction as already described. Much importance has been attached to adhesions in regard to intestinal stasis and alimentary toxæmia. But it has been shown that they can be found in the majority of persons of all but the youngest ages, being most frequent about the colon, and especially the ascending colon and hepatic flexure, and that even in foetal life an adhesive process sets in at the splenic and hepatic flexures, and in some cases fixing the ileum in the pelvic fossa. Their action in impeding the flow of the bowel contents is open to investigation by X-rays after a bismuth or barium meal.

Symptoms. When there is little or no fluid the abdomen may present irregular resistance where the intestines are matted together. Otherwise the symptoms are those of the primary disease.

Diagnosis. The mere diagnosis of chronic peritonitis is not sufficient. It is necessary to find out the primary cause, and the **Prognosis** and **Treatment** depend on this. (*See also Ascites.*)

TUBERCULOUS PERITONITIS

Ætiology. Tuberculous peritonitis occurs at all ages, but most commonly in children and young adults. It is very commonly associated with tubercle in other parts of the body. It is hence often secondary to pulmonary phthisis, to tuberculous ulceration of the intestine, to caseous mesenteric glands, and to diseases of the pelvic organs—*e.g.* the Fallopian tubes, or the testes and vesiculæ seminales. It may form part of an acute general tuberculosis. Sometimes, no doubt, tubercle bacilli may pass through the bowel wall when there is no obvious lesion.

Pathology. There are four types of tuberculous peritonitis: (1) The *ascitic* type. The surface of the peritoneum is covered with small, flat whitish grains, from 2 to 5 mm. in diameter, slightly raised above the surface, and closely aggregated together. These tubercles are most abundant on the under-surface of the diaphragm and in the flanks. There is an exudation of serous fluid, which may amount to several pints, and the abdomen may be as much enlarged as it is in ascites from cirrhosis or heart disease. More rarely the liquid is sero-purulent or purulent. (2) The *adhesive, fibrinous* or *plastic* type. The exudation of fluid is much smaller in quantity, and fibrin is deposited extensively between the coils of intestine. Organisation takes place so that the coils adhere together and the peritoneal cavity becomes obliterated. In later stages firm fibrous tissue is formed. The tubercles may not be at all obvious. (3) The *caseous* type. The tubercles become larger, and in places they coalesce to form yellow caseous lumps. This often occurs in the great omentum, which becomes contracted up,

forming a sausage-shaped mass across the abdomen. Extensive ulceration of the bowel occurs in this form. The adherent intestines may open into one another through the bases of the ulcers, and render it impossible to trace the natural course of the alimentary canal. Perforation may take place, causing acute general peritonitis, or there may be collections of pus shut off from one another in different parts of the peritoneal cavity. The mesenteric glands are often caseous, and when these form large palpable lumps, the type is often called (4) *tabes mesenterica*, which term is used to denote a primary tuberculosis of the mesenteric glands, involving the peritoneum secondarily. The glands may suppurate and burst externally or into the peritoneal cavity. It must be remembered that cases often do not correspond to these types in any hard-and-fast way. Mixtures of all of them may be present, and the case may change from one type to another during the course of the illness.

Symptoms. The symptoms are sometimes *acute*, and the case is similar in every respect to acute peritonitis from other infections. More often they come on insidiously, consisting of pain or discomfort in the abdomen. The patient loses strength and flesh; there is irregular pyrexia; the appetite is diminished, and the bowels are irregular, but often loose and undigested. The abdomen may be enlarged from ascites. In the adhesive form the abdomen is also swollen and presents to palpation increased resistance in certain parts, or a doughy sensation. In the caseous form and in *tabes mesenterica* there are firm rounded masses with a more or less definite outline. Such tumour-like masses often occupy the lower half of the abdomen, reaching perhaps higher on one side than on the other; they are irregular or nodular on the surface. Sometimes the indurated masses of tuberculous infiltration are felt as bands running across the abdomen. Thus the thickened omentum often forms a transverse band at its upper part, and the tissue about the obliterated urachus forms a vertical band below the umbilicus. Occasionally the abdomen is retracted from the excess of fibrous tissue and consequent contraction. Tuberculosis of the abdominal lymphatic glands with obstruction of the lymphatics causes steatorrhœa.

Diagnosis. A distended abdomen associated with a chest showing undue prominence of the ribs and recession of the intercostal spaces from wasting is very characteristic of advanced tuberculous peritonitis. Obvious veins may be seen on the surface of the abdomen, and there is some tenderness. Cæcal tuberculosis and peritonitis may resemble an appendix abscess of long standing, or a case of abdominal Hodgkin's disease. The acute forms may resemble one of the enteric fevers.

There are three conditions in children, characterised by wasted limbs and a large abdomen, which are liable to be spoken of as "consumption of the bowels." They are tuberculous peritonitis and tuberculosis of the abdominal lymphatic glands, celiac disease, and simple indigestion with diarrhœa. Of these the last is the most common. The X-rays may help in doubtful cases. In tuberculous peritonitis, owing to the adhesions, the opaque meal forms small aggregations at irregular points in the small intestine, whereas normally it passes uninterruptedly through to the end of the ileum. The infiltrated omentum may be mistaken for the lower part of an enlarged liver, but the resonance of the stomach above it should prevent this error. Sometimes, but not always, the diagnosis may be confirmed by the presence of tubercle in other parts of the body. In children or young people, a simple ascites, otherwise unexplained, is likely to be tuberculous, but it is often difficult to distinguish from the ascites of hepatic cirrhosis, which indeed sometimes co-exists; and it has often been mistaken for an ovarian cyst until operation has proved the contrary. The liquid withdrawn by paracentesis may be tested by inoculation into a guinea-pig, or tuberculin may be used (see p. 170).

Prognosis. This is more hopeful than the prognosis of many other tuber-

culous lesions, and many patients treated early have apparently recovered completely. Not only does liquid become absorbed, but large masses of induration, infiltration, or matting have disappeared entirely in some cases.

Treatment. Rest in bed is important, and this should be combined with fresh air, as described in the sanatorium treatment of phthisis. Exposure of the body to sunlight (*heliotherapy*) is a valuable method of treating non-febrile cases not only of tuberculous peritonitis, but also of tuberculosis of the lymphatic glands, bones and joints. The extent of body surface exposed is gradually increased from day to day, beginning with the feet and passing upwards, until finally the whole body is exposed for two or three hours a day. The head is kept covered. Albinos and people whose power of responding by producing pigment is limited are not very suitable subjects (89). Cod-liver oil and general tonics may be used internally, and the diet should be easily digestible. Mercurial ointment applied to the abdomen is an old method of treatment. Excess of fluid may be removed by paracentesis; but a laparotomy is an even better method, as it enables localised collections of fluid to be evacuated. Steatorrhœa should be treated by reducing the fat in the diet.

PERITONEAL EFFUSIONS AND CONTENTS

Liquid effusions into the peritoneal cavity are: (1) The serous, serofibrinous and purulent liquids which result from inflammation or peritonitis. The names *polyorrhomenitis* (*ὀρρός*, serum) or *polyserositis*, or Concato's disease, are given to the condition of simultaneous inflammations of two or more of the four great serous membranes, pericardium, pleuræ, and peritoneum. This association may occur in tuberculous, streptococcal and pneumococcal infection, and in acute rheumatism. It must be distinguished from Pick's disease (*q.v.*). (2) The liquids effused in the different forms of hepatic, cardiac or renal dropsy, and the chylous and chyloform liquids sometimes present. (3) Liquids provided by the rupture of vessels, or other adjacent structures. Thus (*a*) blood may be found in the peritoneal cavity as the result of traumatism, rupture of an aneurysm, hæmorrhagic pancreatitis, embolism or thrombosis of mesenteric vessels, rupture of vessels in carcinomatous growths, extra-uterine pregnancy and other conditions. (*b*) Bile may reach the peritoneum during rupture of a hydatid cyst in the liver, and possibly from rupture of the gall bladder. (*c*) A hydatid cyst, whether simple or suppurating, may rupture and discharge its contents into the peritoneum. (*d*) Pus from abscesses and (*e*) the contents of any of the hollow abdominal viscera may from traumatism or disease be passed into the cavity, for instance, those of the stomach, intestines or bladder, etc.

NEW GROWTHS IN THE PERITONEUM

One of the most common growths in the peritoneum is *carcinoma*, secondary to disease in the viscera, especially the stomach and the ovary. It occurs mostly at an advanced age. It occurs in the form of flat circular deposits, covering the abdominal surface, and, like tubercle, it is most abundant on the diaphragm and in the flanks; similarly the omentum may be thickened and infiltrated, and eventually large carcinomatous nodules may occur all over the abdomen. *Colloid carcinoma* is present in a certain number of cases. Considerable liquid effusion is commonly present (*carcinomatous peritonitis*), and blood is not infrequently mixed with it, so that it acquires a brown, brownish-red, or even red colour. Occasionally nodules of carcinoma are felt in the skin around the umbilicus, and the glands in the groin may be infiltrated with the same growth. Colloid carcinoma must be distinguished from so-called *pseudo-myxoma peritonei*. If an organ, *e.g.* the appendix, affected with catarrhal inflammation, ruptures, mucus may be extruded through the opening into the peritoneum, forming large masses, to which this name is given.

Sarcoma is another common form of malignant disease ; it occurs in the retro-peritoneal tissues, in the omentum, mesentery, or broad ligament. Retro-peritoneal *myxo-sarcoma* may form very large tumours.

Symptoms. Apart from the symptoms of chronic peritonitis already described, these depend on the seat of the primary growth.

Prognosis is absolutely unfavourable, and **Treatment** must be directed to the relief of symptoms, the temporary removal of fluid when it is considerable, or an operation for obstructed bowel. *Sarcoma* may do well with deep X-ray therapy.

DISEASES OF THE BLOOD, SPLEEN, AND LYMPHATIC SYSTEM

EXAMINATION OF THE BLOOD

Coagulation Time. The determinations are carried out at blood temperature. Gibbs' clinical blood coagulometer is the instrument recommended (1). A drop of blood is made to travel round a platinum wire loop, and its movement stops when coagulation takes place. The coagulation time of the first drop obtained from a prick varies from about 100 to 170 sec. (average 128 sec.). With later drops the time is shorter (25—55 sec.). This is because, at first, the bruising of the tissues liberates thrombokinase, while, later on, platelets become agglutinated in the wounded vessels and give rise to extra prothrombin (2), factors which increase the speed of clotting.

AVERAGE VALUES OF SOME NORMAL CONSTITUENTS OF BLOOD AND URINE

	Whole Blood. (Fasting).	Urine. (On ordinary diet).	
	Mgm. per 100 c.c.	Mgm. per 100 c.c.	Grams. per 24 hrs.
Amino-acid N . . .	Up to 6	6	0·06
Chlorine . . .	270-300	600	Up to 10
Cholesterol . . .	120-200		
Dextrose . . .	80-100		
Non-protein N . . .	3		
Uric Acid . . .	Up to 4	57	1
Urea . . .	19-32	2,000	20-30
	Plasma.		
Chlorine . . .	352-383	600	Up to 10
Albumin . . .	4,400		
Globulin & Fibrinogen	2,630		
Alb.-glob. ratio . .	1·67 to 1		
Fibrinogen . . .	0·2-0·4		
Inorg. phosphorus .	3	90	0·9
	Serum.		
Calcium . . .	9·6	15-17	0·3
Magnesium . . .	3·2	6	0·16
Potassium . . .	19·5	200-250	Up to 4
Sodium . . .	335	300	Up to 5
Alkaline Reserve . .	53-75 c.c. CO ₂		
Oxidised sulphur . .			
Inorganic . . .	0·5-1·1	180	2·3
Ethereal . . .	0·1-1·0	15	0·2
Unoxidised sulphur .	1·7-3·5	15	0·2

Note. There is no ammonia in blood; the ammonia nitrogen content of the urine is usually 10 times the amino-acid nitrogen.

Bleeding Time. The blood from a prick is dried off with blotting paper without pressure every quarter or half minute. Normally, the bleeding ceases in one to two and a half minutes; in disease it may be prolonged up to thirty minutes or even several hours.

Sedimentation Rate. Oxalated or citrated blood is drawn into a glass tube of at least 2 mm. bore, so as to form a column 10 cm. high. The normal rate at which the corpuscles sink is such that there is left a clear column of plasma in the top of the tube, measuring up to 0.4 cm. in 15'; 1.0 cm. in 30'; 2.5 cm. in 60'. The determinations are best carried out in an incubator at 37° C. A rapid sedimentation rate suggests infection, *e.g.* focal sepsis; but anæmia and nephritis must be excluded.

Fragility of Corpuscles. In some diseases it has been found that the fragility of the red corpuscles is greater than normal, or, in other words, that the corpuscular or globular resistance to hæmolysis by dilute fluids is less. For this determination a few cubic centimetres of blood are mixed with an isotonic solution of oxalate of potassium (pot. oxal. 0.28 gramme, sod. chlor. 0.8 gramme, aq. dest. 100 grammes), centrifuged, the plasma decanted, and the corpuscles washed in a solution of 0.9 per cent. of sodium chloride, and then tested with sodium chloride solutions of different strengths. Washed normal red corpuscles show slight hæmolysis in 0.45 per cent. sodium chloride, and complete hæmolysis in 0.35 per cent. Abnormally high fragility is shown if hæmolysis occurs with stronger solutions, as is the case in acholuric jaundice.

Enumeration of Corpuscles, or Blood-count. This is effected by the *hæmocytometer* of Thoma-Zeiss or Bürker-Zeiss.

The former consists of a glass slide on which a "cell" is constructed $\frac{1}{10}$ mm. in depth and ruled at the bottom into squares measuring $\frac{1}{20}$ mm. in the side, which are again ruled into groups of sixteen small squares. In a specially constructed pipette the blood is diluted to the extent of 1 to 100 by a saline solution (sodium phosphate or chloride) which does not injure the corpuscles; and a drop of this is placed in the cell and covered with thin glass. The corpuscles settle down upon the squares, each of which corresponds to $\frac{1}{40000}$ cubic millimetre. The red corpuscles in several groups of sixteen squares are counted, and the total multiplied by 100 (the dilution) and 4,000 (representing the volume of fluid over each small square), and divided by the number of small squares counted, gives the corpuscles in a cubic millimetre. In Bürker's instrument, which is preferable to that of Thoma-Zeiss, the cover glass is first of all arranged in position by clamps, and the diluted blood is then run in by capillary attraction. Bürker's method of effecting dilution is also much superior, but this is not yet much used in this country. A second pipette provides for a dilution of 1 in 10 with 0.9 per cent. acetic acid, by which the red corpuscles are rendered invisible.

The average number of red corpuscles per cubic millimetre is usually taken to be 5,000,000 for males and 4,500,000 for females. Actually in London the average for males is 5,430,000 and the range, within which about 90 per cent. of normal values lie ($2.5 \times$ standard deviation), is 4,660,000–6,190,000; for females, 5,010,000 and the range 4,120,000–5,910,000.

The average hæmoglobin for men in London is 105 per cent., corresponding to an oxygen capacity of 19.5 per cent. and 14.5 grm. hæmoglobin; the range within which 90 per cent. of normal results lie ($2.5 \times$ standard deviation) is from 96 to 115 per cent. The average hæmoglobin for women is 98 per cent., and the range 87 to 110. These high values may be due to carbon monoxide in the atmosphere from motors.

The number of leucocytes is from 4,000 to 9,000 per cubic millimetre when counted in the morning; the maximum is 12,000 in the afternoon (*see p. 427*).

Platelet-counting. A drop of sterile 2.5 per cent. solution of sodium citrate is placed on the finger, and the latter is pricked through the drop, so that blood diffuses out into it. The mixed blood and citrate are examined fresh with the

microscope, drying being prevented by ringing the cover-slip with vaseline. If the number of red cells per cubic millimetre is known, the number of platelets can be determined from the ratio of the two in the film. The normal figure varies between 200,000 and 500,000.

Estimation of Hæmoglobin. For clinical purposes Haldane's hæmoglobinometer is the best to use. Two tubes are provided. One of them, which is the standard, contains a 1 per cent. solution of normal blood saturated with carbonic oxide, and is hermetically sealed. The other tube is graduated in divisions up to 100, and in this a measured quantity of blood is diluted till it matches the colour of the standard after saturating with coal-gas to convert all the hæmoglobin into CO-hæmoglobin. The figure on the scale which the solution then reaches represents the percentage amount of hæmoglobin. The Dare hæmoglobinometer is standardised on the same scale as the Haldane instrument; but other instruments are differently standardised.

Colour Index. The concentration of hæmoglobin in the corpuscles shows some variation in different diseases of the blood; but the size of the corpuscles varies much more. The percentage of hæmoglobin is less than that of the corpuscles if individual corpuscles are smaller than normal; the hæmoglobin percentage is greater if the corpuscles are larger than normal. This relation of the hæmoglobin percentage to the corpuscle percentage is called the *colour index*, and it may be less or greater than 1, according as the cells are on the average smaller or larger than normal (3). Thus with hæmoglobin 40 per cent., corpuscles 50 per cent., the colour index is $\frac{4}{5}$ or 0.8. The average colour index for men in London is 0.97 and the range 0.89–1.06, and for women the average is 0.98 and the range 0.87 to 1.1.

Microscopic Examination of the Corpuscles. Though a clinical diagnosis may often be made from an unstained film, stains, such as Jenner's or Leishmann's, should be ordinarily employed. To stain reticulocytes, an alcoholic solution of cresyl blue is evaporated to dryness on a warm slide; a drop of blood is mixed with the dye; it is then spread out and allowed to dry and examined with an oil immersion lens.

The different corpuscles which may be seen in health and disease are illustrated in Plates 33, 34, 35, 36, B, C.

Red Corpuscles or Erythrocytes. The normal red corpuscle measuring in diameter 7.5μ ; small corpuscles, or *microcytes*, from 2 to 6μ ; large corpuscles, or *megalocytes*, from 8 to 15μ . Inequality in the size of the red cells is called *anisocytosis*. In addition there are misshapen, distorted, often pear-shaped corpuscles, or *poikilocytes*; fragments of corpuscles are called *schizocytes*; nucleated red corpuscles (*erythroblasts*), divided according to their size and shape into *normoblasts*, *microblasts*, *megaloblasts*, and *poikiloblasts*, also occur.

Nucleated red cells occur normally in the bone marrow. Their presence in the blood indicates increased production in the marrow.

Free nuclei from rupture of erythroblasts may be seen. *Reticulocytes* are red cells containing a basophil reticulum; they are seen in the early stage of recovery in pernicious anæmia (see Plate 36, B, p. 433); *polychromasia* is another name for reticulocytosis. *Punctate basophilia* or stippling of the red cells is an allied condition, considered further under lead-poisoning. A *metocyte* is a megaloblast in which the nucleus shows signs of mitosis.

Leucocytes. The white cells, of which there are several varieties, fall into two groups: (1) *granular* cells, sometimes called *leucoid*, viz., *polymorphonuclear* cells with small acid-staining granules in the cytoplasm and variable nucleus, *eosinophil* cells with coarse granules and horseshoe-shaped nucleus, and *mast* cells with granules staining purple and faintly basophil nucleus; (2) non-granular, or *lymphoid*, cells, viz. *lymphocytes*, large and small, with large, round, strongly basophil nucleus and scanty cytoplasm, which is only faintly stained, and *large mononuclear* or *hyaline* cells or *monocytes*, as they are now usually called, with

anæmia which especially occurs in constipated girls and young women between the ages of fourteen and twenty-four, though a similar condition is exceptionally seen in boys. There has been a gradual decline in the incidence of chlorosis since the beginning of the century, and this is probably due to the abolition of tight-lacing with its pressure on the liver, as well as to the better conditions under which women's work is carried on and to the greater amount of fresh air and exercise taken (6). It was commonest among those in domestic service.

Symptoms. Chlorosis is a microcytic anæmia; a blood count shows a low colour index, the hæmoglobin being reduced more than the red cells. Normoblasts, reticulocytes and schizocytes may be seen in serious cases. The leucocytes are normal. There is amenorrhœa. The gastric juice contains free HCl. Optic neuritis occasionally occurs, and may be followed by atrophy, exceptionally also ocular paralysis, retinal embolism, and retrobulbar neuritis,

Prognosis and Treatment. See Simple Achlorhydic Anæmia.

SIMPLE ACHLORHYDIC ANÆMIA

This disease affects women much more commonly than men, and women about the child-bearing age—most of all from forty to fifty; but it does occur in children and in the aged (33). However, it must be remembered that 32 per cent. of healthy men and women have achlorhydria above sixty years.

Symptoms. This is a microcytic anæmia, the blood showing a low colour index. Like pernicious anæmia it is associated with achlorhydria; but there is no excess of bilirubin in the blood, so that Van den Bergh's test is negative, and there are no changes in the spinal cord. The spleen is large and there is frequently glossitis and the inflammation spreading from the tongue on to the back of the pharynx; there is sometimes dysphagia. The nails are concave (spoon-shaped) and thin with longitudinal ridging (*koilonychia*). The anæmia is probably due to defective absorption of iron in the alimentary tract and the absence of hydrochloric acid in the gastric juice may be partly responsible.

Diagnosis. This depends on observing achlorhydria with an anæmia of low colour index, without obvious cause, such as bleeding.

Prognosis. This is good with efficient treatment.

Treatment. Iron must be given in large doses. The scale preparation, iron and ammonium citrate, containing ferric citrate, is a favourite; but a drachm must be given daily; iron is only absorbed and acts in the ferrous condition (7), and so it is better to use ferrous iron. Pil. ferri. (Blaud's pill), a mixture containing ferrous sulphate and sodium carbonate (5 to 15 grains), is well known; it may be given in powdered form. The difficulty of prescribing ferrous sulphate in solution is that it is oxidised; but this can be hindered by dissolving it in 10 per cent. glucose solution, or acid. sulph. dil. 5 minims to 5 grains of ferrous sulphate may be used instead.

In many cases it will be desirable to find out as soon as possible whether the treatment is effective; for this, a reticulocyte crisis is looked for as described under pernicious anæmia. Most iron preparations contain small amounts of copper; but if necessary, this may be prescribed as a $\frac{1}{2}$ per cent. solution of copper sulphate 3–5 c.c. daily. Care must be taken to see that there is no hypothyroidism and that there is in the diet plenty of vitamin C, best given as orange and lemon juice. The anæmia in scurvy has been observed before hæmorrhage takes place. It is generally agreed that all forms of iron given by injection are valueless, and it is unnecessary to give arsenic; but liver or liver extract sometimes helps though it should not replace iron. If a laxative is required pil. aloes et ferri. (4–8 grains) containing ferrous sulphate may be useful. The naturally occurring chalybeate waters contain ferrous carbonate held in solution by extra CO₂, and these are valuable when taken by mouth fresh at the spring. In severe cases rest in bed during treatment is essential and blood transfusions may be valuable.

PERNICIOUS ANÆMIA

(Addison's Anæmia, Glossitic Anæmia)

Cases of this disease were first described by Addison under the name of *idiopathic anæmia*, because they presented distinctive features, and he was unable to find a cause for them. Later Biermer and other Continental writers described similar cases, under the name of *progressive pernicious anæmia*.

Ætiology. It affects both sexes equally, and 85 per cent. of cases are over the age of forty; and there is a hereditary tendency to the gastric changes responsible for this disease (17).

Morbid Anatomy. Besides the universal pallor of the organs, one of the most constant conditions *post-mortem* is fatty degeneration of the heart, which shows itself by alternate dark and pale striations of the muscle as seen through the endocardium (tabby-cat striation). It is due to deficient oxygen supply, owing to the diminished amount of hæmoglobin in the blood. It occurs in the left ventricle and the papillary muscles. There is also fatty degeneration of the liver and kidneys, and of the intima of the arteries. Hæmorrhages are found not only in the retina, where they have been seen during life, but in the serous membranes, the endocardium, the mucous membrane of the stomach, the lungs, the surface of the brain, and other parts. Fenwick originally observed changes in the stomach typical of gastritis, *q.v.* The spleen is sometimes enlarged, and of dark red or purple colour. The marrow of the bones has been found to be excessive in amount, of a reddish-purple colour, with large numbers of nucleated red corpuscles, especially megaloblasts. There is, moreover, an abundant deposit of iron in the peripheral zones of the lobules of the liver, in the spleen and in the kidneys, as can be shown by the organ turning blue with potassium ferrocyanide and dilute hydrochloric acid. In cases with spinal symptoms a degeneration of the lateral and posterior columns is found after death.

Pathology. The following features of the disease must be related in any consideration of its pathology: (1) The excess of urobilin in the urine, the deposit of iron in the liver, and the presence of bile pigment in the blood, which gives Van den Bergh's indirect test. Similar features have been obtained by injecting poisons such as saponin, pyridine, etc., into animals. (2) The hypertrophy of the red marrow with the irregularity in size and shape of the red cells and the presence of megalocytes and sometimes megaloblasts in the circulating blood. The disease is a *macrocytic anæmia*. The biochemical constitution of the red cells is also altered; there is an increased H ion concentration in the corpuscles, probably due to an increase in the phosphoric acid esters, so that the potential difference between cells and plasma is 28 millivolts, instead of eight or nine (12). (3) The absence of free HCl in the gastric juice, which is due chiefly to a gastritis, since the mineral chloride and pepsin are also low, though never completely absent (13); probably there is always a little "active" HCl present (see Fig. 47, p. 331). Inflammation elsewhere in the alimentary tract is shown by the characteristic glossitis; while the diarrhœa in certain cases may be due to an enteritis. (4) The curative effect of liver extract when given by mouth.

Up till recently the disease was considered to be due to a primary hæmolysis; but it is doubtful whether hæmolysis is at all prominent; if all the excreted bilirubin came from broken-down corpuscles, it would mean that the corpuscles of the blood would have to be regenerated with impossible rapidity; the excretion of bilirubin is very variable, while the blood picture is constant; the blood picture is very unlike acholuric jaundice, which is primarily a hæmolytic disease; the red cells may survive as long in pernicious anæmia as in health. Instead, the disease is primarily one of faulty formation of blood cells, as described on p. 429. Without the hæmatinic principle the marrow cannot produce and discharge perfect red cells into the circulation; they remain densely packed up in the marrow, giving it its red colour. On giving liver a flood of immature cells

still no response, the preparation is probably inactive. These preparations are prescribed in amounts equivalent to the original weight of liver from which they are prepared. Liver extracts are now available that need only be injected once every four to eight weeks to keep the patient in health. The daily administration of the extract from 1 lb. of liver may be required in the early stages, although the amount may be diminished to $\frac{1}{4}$ lb. or less later on. Periodical blood counts or the Van den Bergh's test are advisable. Within a few days the patients begin to feel better and eventually may develop an unusually florid red complexion, a great contrast to their previous washed-out, yellowish complexion. Sources of sepsis, whether due to teeth, tonsils, nasal sinuses, etc., should also be dealt with. It may be advisable to give a blood transfusion at the beginning of treatment in serious cases, especially if the temperature is high. The "extrinsic factor" is present in wheat germ and alcoholic extract of brewer's yeast, and marmite (5), and if there is sufficient of the intrinsic factor present in the stomach, giving these substances will be efficacious; or after the preliminary treatment there may be sufficient of the intrinsic factor to allow marmite to be given alone (6).

Other Megalocytic Anæmias. These resemble, and some of them may be considered identical with, pernicious anæmia; the bilirubinæmia is often not marked, and sometimes there is bilirubinæmia and a microcytic anæmia.

The causes are: resection of the stomach for ulcer or carcinoma, faulty intestinal absorption, gastro-colic fistula, resection of the small intestine, intestinal stenosis and tuberculous ulceration, fatty diarrhœa, including coeliac disease, sprue and infection with *Diphyllobothrium latum* (18). In many of these cases there is achlorhydria, which may clear up when the patient improves.

Aplastic Anæmia. This disease may result from poisoning with salvarsan and other benzol compounds (20), and from excessive exposure to X-rays. Infection of the bone marrow may be secondary (21). The red corpuscles and hæmoglobin are reduced to about 20 per cent. of the normal, and the colour index is about unity; nucleated red cells are not frequent; there is leucopenia, due to a diminution in polymorphonuclear cells. The bone marrow differs from that of pernicious anæmia in being remarkably pale and fatty, and in wanting all signs of blood regeneration. Thus there is *aplasia* of the bone marrow, which is regarded as the primary cause of the disease. In some cases (*Aleukia hæmorrhagica*) there is also a great diminution or complete absence of blood platelets, and associated with this there is a severe hæmorrhagic tendency with delay in the bleeding time, but not in the clotting time; a condition identical with a severe type of purpura (see p. 445). The treatment with liver is not successful, as the fault occurs at the earliest stage of blood formation (Fig. 53). Repeated blood transfusions, up to 300, have kept one patient alive for seven years up to the present (34).

Agranulocytosis (Neutropenia). This is an allied condition characterised mainly by a diminution of leucoid (granular) cells and often accompanied by severe infection of the throat—*agranulocytic angina*—such as Vincent's angina or other infection. It is suggested that the blood condition is primary, and that infection takes place because the neutropenia means diminished resistance. There may or may not be aplastic anæmia as well. The lymphocytes may remain normal or show some reduction; but there may be a monocytosis at first (10). Relapses may take place over years, often with infections. It has been stated that the increase of this disease has synchronised with the popularity of amidopyrina (pyramidon) or a combination of this drug with a barbiturate (11). The bone marrow shows hypoplasia with absence of granulocytic cells. In granulocytic angina the mortality is over 75 per cent., but when treated with pentose nucleotide, K96, to stimulate polymorph formation it has been reduced to 25 per cent. (8), though some cases do not respond (9).

The Anhæmopoietic Anæmias of Childhood. These in a general way resemble adult anæmias.

The *megalocytic anæmias* are rare, but they have been found in infection by *Diphyllobothrium latum* and in coeliac disease from absence of the extrinsic factor, so that cure has resulted from giving marmite which contains it.

Of the *microcytic anæmias* attention may first be directed to the anæmia that may result from scurvy and cretinism, that is cured by vitamin C and thyroid respectively. Coeliac disease usually causes anæmia of this type. The commonest anæmias are *nutritional*, and an important factor is that, though there is plenty of iron in the liver and spleen at birth, the store diminishes progressively till the end of lactation, because milk contains but little iron, though breast milk is richer than cow's milk. Anæmia of infancy may be due to deficient *ante-natal* storage of iron from anæmia of the mother, premature birth before iron storage is complete, or twin pregnancy when the demand for iron is nearly double; or from a deficient *post-natal* supply of iron, due to deficiency of iron in the milk or prolonged milk feeding. Treatment is the same as for simple achlorhydric anæmias; ferrous sulphate (4 grains) three times a day dissolved in water with glucose and perhaps a little copper; the latter appears to act by helping to build up the iron which is stored in the liver into hæmoglobin (15).

In previous editions of this book Van Jaksch's *anæmia infantum pseudo-leukæmica* (splenic anæmia of infancy) has been described as a separate disease. The blood shows a secondary anæmia with an increase of leucocytes up to 40,000 with a few myelocytes; the liver and spleen are enlarged. The condition probably represents the infantile response on the part of the marrow to a number of factors that may cause anæmia, especially infection, and one patient developed typical acholuric jaundice (16).

HÆMOLYTIC ANÆMIAS

One group of hæmolytic anæmias is familial, consisting of *acholuric family jaundice*; sickle-cell anæmia, met with in negroes with jaundice, glandular enlargements and ulcers on the legs; the very rare *erythroblastic* anæmia of infants, and *icterus gravis neonatorum* already described. Then there are the various infections of which gas gangrene causes the worst degree of anæmia, chronic suppuration, prolonged fevers, streptococcal disease, including puerperal fever, acute rheumatism, infective endocarditis commonly associated with aortic regurgitation, tuberculosis, syphilis including paroxysmal hæmoglobinuria, malaria; then there are poisons such as aniline derivatives, lead poisoning and repeated blood transfusion, and finally pregnancy.

Symptoms. Hæmoglobinuria and jaundice follow if blood destruction is rapid; the colour index depends on the type of bone-marrow response, as already described, and with a vigorous response there is reticulocytosis and nucleated red cells are seen. There is often enlargement of liver and spleen and occasionally of the lymph glands.

ACHOLURIC JAUNDICE

(Chronic Splenomegalic Hæmolytic Jaundice)

In this comparatively rare form of jaundice there is no obstruction of the ducts, for the fæces retain their normal colour, and the urine is, except in aggravated attacks, free from bile pigment; but it contains urobilin. The blood serum, on the other hand, contains bile pigment, but is free from urobilin or urobilinogen. It gives Van den Bergh's indirect test. The primary cause is a defect in the red cells, which show an increased fragility (*see p. 423*). These cells are destroyed in numbers by the spleen, and the bile pigment in the blood comes from

the hæmoglobin of these cells. The patient becomes anæmic if compensatory blood regeneration is insufficient. Histologically, the spleen pulp contains an enormous number of normal-looking red cells, and in the active hæmolytic stage there is free iron pigment; the sinuses are relatively empty. The disease occurs in two forms, congenital and acquired.

Acholuric Family Jaundice. The jaundice, which occurs in several members of a family, is often noticed immediately after birth, or develops slowly at a later time; it may persist for years, or it clears up and recurs from time to time. The patient is anæmic; the red corpuscles are reduced to 3,000,000 or 3,500,000 and present moderate degrees of poikilocytosis, anisocytosis, polychromasia, and punctate basophilia; while nucleated red cells are present. A reticulocytosis of 5 per cent upwards is characteristic. The red cells have a smaller diameter but are thicker than normal. The hæmoglobin is reduced to 50 or 45 per cent., and the colour index is slightly below unity. The leucocytes are generally fewer than normal, but occasionally there is leucocytosis; the large lymphocytes are sometimes in excess, and a few myelocytes may be present. The spleen is enlarged, and appears to grow harder with the progress of the case. The liver is only slightly enlarged, and has not been known to be cirrhotic; it often enlarges during exacerbations and diminishes afterwards. The patients, as children, are not generally stunted as in splenomegalic cirrhosis (*see* p. 397), nor are the fingers clubbed. Moreover, they may be little troubled by their complaint, and may live for many years. New erythroblastic tissue may be formed outside the bone marrow; in the chest these masses may on X-ray be confused with intrathoracic neoplasm. There is a tendency to gallstones.

Acquired Acholuric Jaundice. In this form of the disease the symptoms come on insidiously in adult life; the anæmia is often pronounced, and the red corpuscles may fall to 2,000,000 or 1,500,000 or less; the colour index is sometimes above unity, as in pernicious anæmia; the jaundice is often very slight; the spleen is enlarged. The fragility of the red corpuscles is normal in a few cases. In both forms of the disease, but particularly in the acquired form, exacerbations of the hæmolysis take place, the blood picture resembling pernicious anæmia.

Treatment. Liver treatment, as for pernicious anæmia, should be tried, especially if the red cells show the same characteristic changes. Removal of the spleen has brought about recovery in both acquired and congenital cases, and this should be carried out if the anæmia is severe. It is noteworthy that if the spleen is removed in healthy animals the normal fragility of the corpuscles is diminished; but in acholuric jaundice the fragility is not diminished after operation.

Lederer's Hæmolytic Anæmia is a rare type of anæmia, more common in young children, in which a hæmolytic anæmia develops with great suddenness. The liver and spleen are enlarged. There is usually a leucocytosis which may reach 40,000 per cubic millimetre. Often gastro-intestinal symptoms are present. Treatment by transfusion usually leads to a rapid recovery.

SPLENIC ANÆMIA

This name is given to a number of conditions in which great enlargement of the spleen is associated with anæmia. Their varied pathology is described on p. 454; but in some cases the condition is undoubtedly syphilitic, and high blood pressure in the portal area is important.

Symptoms. The first event is either a general anæmia or an attack of hæmatemesis, or some complaint of pain in the left side, probably due to attacks of perisplenitis. When first observed the spleen has often reached a great size, and in the course of the illness it may be large enough to extend forwards to the umbilicus and downwards to the iliac crest. The anæmia is considerable, of chlorotic type, the red corpuscles ranging from 2,000,000 to 3,000,000, and the hæmoglobin from 35 to 50 per cent. The colour index is less than 1, but not

usually lower than 0.6. The leucocytes are generally in less number than normal (leucopenia), often only 4,000 or 5,000 per cubic millimetre. Normoblasts and a few megaloblasts may be present.

The disease runs a long course, often three or four years, sometimes ten or twelve years, and the anæmia slowly increases. The hæmatemesis may be repeated, and other hæmorrhages may occur, such as epistaxis or retinal hæmorrhage. The liver is enlarged, and there are digestive troubles; but there is no enlargement of the lymphatic glands, nor, as a rule, pyrexia. In some cases there is marked pigmentation of the skin. It occurs in both sexes, and at all ages from childhood up to late middle age. In some cases after a long time the liver becomes still more enlarged, and definitely cirrhotic. Ascites then follows, though it also sometimes occurs without cirrhosis. The supervention of definite cirrhosis of the liver with ascites is commonly called *Banti's disease*.

In other cases splenic anæmia has been associated with thrombosis of the spleen veins. Chronic perihepatitis and perisplenitis are invariably present in long standing cases.

Diagnosis. The disease may be confounded with aleukæmic leukæmia, with pernicious anæmia, and with infective endocarditis. Its characteristic features are the anæmia of chlorotic type, the leucopenia, the large size of the spleen, the absence of leukæmia and of enlargements of the lymphatic glands, the long duration, and the occurrence of hæmorrhages. A confusion with malignant endocarditis is possible, because in this last disease the spleen may be very large, the anæmia may be pronounced, and purpura and hæmorrhages may occur; while hæmic murmurs may be present in splenic anæmia.

A diagnosis of Banti's disease may be too readily made in a case of cirrhosis with usually large spleen; its resemblance to Egyptian splenomegaly (*q.v.*) should be remembered.

Treatment. Iron and arsenic are of little value; and if after a period of observation the diagnosis is established the removal of the spleen is justified. Although it is not free from the danger of hæmorrhage, cases have been completely successful. Röntgen rays may be tried, as in leukæmia. Blood transfusion is a valuable palliative measure.

LEUKÆMIA

(*Leucocythæmia*)

These names are given to those cases of disease in which there is a considerable and persistent increase in the total number of leucocytes in the blood, or in a certain variety of leucocyte (*aleukæmic leukæmia*, see later), associated with changes in the marrow of the bones, in the spleen or the lymphatic glands.

Ætiology. The cause of any form of leukæmia is unknown; it may represent the response of the leucocyte-forming organs to some infection, or it may be merely a sarcoma of the white cells. Occasionally, however, leukæmia follows closely upon some septic condition. The myelocytic variety occurs in men more often than in women, and mostly in middle life, though sometimes in quite young children, but rarely in infants. Lymphatic leukæmia is more common in young people.

Pathology. There is over-production of leucoid cells or of lymphoid cells, giving rise to the two characteristic types of the disease and leading to the flooding of the circulating blood with immature forms of leucocytes. The bone marrow, the spleen and lymph glands, may all take on the function of actively producing leucocytes, in the various types of the disease. As the latter continues, still greater pressure is brought to bear on the depôts where the white cells are manufactured, and the cells are turned out into the blood in a still more primitive form. In certain cases this increased activity of the normal depôts is accompanied by the formation of fresh leucocyte-forming areas in abnormal situations, which will

partake either of myeloid or of lymphoid character. These infiltrations may form nodules beneath the skin, or in different parts of the body (*nodular leukæmia* or *chloroma*, so called from their green colour. See later). There is a close relation to lymphosarcoma (see p. 441).

In leukæmia the basal metabolism is increased. Chemical examination shows a great increase of uric acid in the blood, which is believed to result from the destruction of the leucocytes.

MYELOCYTIC LEUKÆMIA

(*Spleno-medullary, Leucoid, Myeloid, or Granular Leukæmia; Myelocythæmia*)

Condition of the Blood. In well-marked examples of leukæmia the blood is pale and thin as it issues from a wound, and as seen after death it forms pale pus-like clots. The white corpuscles are found in number from 200,000 to 900,000 in the cubic millimetre, instead of 8,000 or 9,000; and the red corpuscles may be from 3,000,000 to 2,000,000, or even as low as 1,000,000. Nucleated red cells are numerous. The colour index is less than unity, but tends to rise if there is a megaloblastic reaction in the later stages, and then the red cells show the characters of pernicious anæmia, while, as far as the white cells are concerned, the picture is that of leucoid leukæmia, with a rather low white count.

In the earlier stage of the disease, especially if the disease is chronic, polymorphonuclear cells are most abundant; most of them are much larger than normal, and some are obviously degenerated. Metamyelocytes with horseshoe-shaped nuclei are also present, and some typical granular and eosinophil myelocytes. The eosinophil and mast cells are increased, while the lymphocytes are not so much increased. At a later stage there are few normal leucocytes present, but there are proleucocytes, myelocytes and promyelocytes and mast cells in abundance. Later still myeloblasts predominate. If the disease runs a rapid course (*Myeloblastic leukæmia*), the more primitive cells, *i.e.* myeloblasts, are seen in large numbers from the beginning, to the exclusion of other types of leucocytes, while the blood platelets are diminished.

Morbid Anatomy. The spleen often weighs 5 or 6 lbs., but a weight of 18 lbs. has been recorded. It is uniformly enlarged, and retains its normal shape; on the surface are often patches of thickening of the capsule, and the organ is more or less adherent to the abdominal wall, diaphragm, or adjacent viscera. On section it often has a brownish rather than a red colour, which is uniform, or marked with paler lines due to thickened trabeculæ. It is smooth, hard and dry. Not infrequently there are large wedge-shaped infarcts, either yellow and caseous or red and hæmorrhagic. The change in the spleen itself is one of great increase of the splenic pulp, which is full of the same cells as are found in the blood, and the outlines of the Malpighian bodies are badly defined; in long-standing cases the stroma becomes more fibrous, and the trabeculæ are increased in thickness.

The *liver* is enlarged, and may reach twice or three times its normal size. It is pale and smooth, and may present under the microscope a dense infiltration with leucocytes (myelocytic infiltration), which for the most part surround the portal vessels in their distribution, but are partly in nodular masses. The vessels also are full of leucocytes. The *kidneys* are pale and may present greyish-white deposits, running like striæ between the cortical tubules. There may be stomatitis or pharyngitis, swelling of the *tonsils*, and of the *follicles* at the root of the tongue, and swelling and superficial ulceration of the follicles, of the intestine. The *thymus*, *thyroid*, and *suprarenal glands* may also be diseased, and tumours in the skin have been recorded. Sometimes the *lungs* present hæmorrhagic infarcts. The *marrow* of the bones is either yellow and pus-like, or pink and firm, the fat of the marrow being replaced by a tissue like that of active marrow, in which myelocytes and nucleated red cells are abundant, with eosino-

phils sometimes, and myeloblasts or large lymphocytes. Besides the occasional hæmorrhage into the brain, diffuse sclerotic changes and scattered areas of acute inflammation have been found in the *brain and spinal cord*.

Symptoms. *Acute Myeloblastic Leukæmia.* This may be the most acute of all the leukæmias, and in one case the whole course of the disease was just under a week (22). The number of myeloblasts in the blood and the anæmia may both increase rapidly. There are numerous hæmorrhages as in the chronic myelocytic forms.

Chronic Myelocytic Leukæmia. One of the first indications of leukæmia, in a great number of cases, is the swelling of the abdomen from the *enlargement of the spleen*, which may have been developing for some time without giving any sign. It may then be found occupying the whole of the left side of the abdomen, forming a firm hard tumour, which extends backwards into the flank, while its anterior margin begins about the ninth costal cartilage, reaches the middle line at the umbilicus level, and not infrequently below this extends 2 or 3 inches to the right. This position is determined by its attachment to its vessels, which compel it to enlarge along the circumference of a circle of which the celiac axis is a centre. The anterior margin is more or less sharp, and presents one or two notches. In earlier stages the spleen only occupies the left hypochondriac region, like the enlargements in malaria, and in some cases of typhoid fever. The *liver* is moderately enlarged, and can be felt for 1 or 2 inches below the right costal margin. The implication of the *bone marrow* is sometimes shown by tenderness on pressure or percussion of the corresponding bone. There may be some delay in the onset of the anæmia with its associated pallor of the skin and mucous membranes.

The altered condition of the blood shows itself in the occurrence of *dyspnœa* and of *hæmorrhages*, which last chiefly take the form of epistaxis, bleeding from the gums and mouth, and purpuric spots under the skin, but also occasionally bleeding from the lungs, stomach and intestines, kidneys, or uterus, or hæmorrhage into the brain. Hæmorrhages also occur in the retina, where they may be seen with the ophthalmoscope associated with white streaks and spots, said to consist of masses of leucocytes; and the retinal veins are often remarkably tortuous (*leukæmic retinitis*).

The course of the disease is generally progressive until its termination in death, and it lasts from six months to five years. Towards the end the pallor increases, the feet and other parts of the body become œdematous, ascites and hydrothorax may be added, the pulse is quickened, and palpitation is frequent. Diarrhœa is occasionally a prominent symptom. There is often some fever. Finally, death takes place from loss of blood, asthenia, diarrhœa, pleurisy, pneumonia, bronchitis or cardiac dilatation, and occasionally from cerebral hæmorrhage.

Diagnosis. The diagnosis depends upon the recognition of an enlarged spleen (see p. 453) and the examination of the blood; the last is absolutely essential. Even when the patient has a good colour there may be pronounced leukæmia.

The **Prognosis** is ultimately unfavourable, but life may be prolonged with efficient treatment. Myeloblastic leukæmia is fatal at an earlier stage.

Treatment. Arsenic is the drug which seems to have given most promise; it must be used perseveringly and in increasing doses as long as it can be borne; and under its use the spleen has diminished in size considerably, and the leucocytes in number. Under treatment by benzol remarkable diminution in the number of the leucocytes and in the size of the spleen has been observed. The daily dose is 30, 60 or 90 minims taken in capsules, with an equal amount of olive oil. This treatment was introduced by Selling, who found that benzol workers often suffered from grave leucopenia. Deep X-ray therapy, applied to the splenic region and to the epiphyses of the long bones (femur) has a decided influence both in reducing the number of the leucocytes and the size of the spleen, which may both become normal. The applications should be stopped when the number of leucocytes has fallen to between 30,000 and 40,000, as their action continues for

some time afterwards. It is also important to see that the leucocytes retain their phagocytic power (35).

Splenectomy has been uniformly fatal from collapse or hæmorrhage.

LYMPHATIC LEUKÆMIA

(*Lymphocytic, Lymphoid, or Non-granular leukæmia ; Lymphocythæmia*)

This is of rarer occurrence than the myelocytic form.

Condition of the Blood. In chronic lymphocytic leukæmia the lymphocytes are increased, while the number of polymorphs and other cells remain about the same. Thus, there may be a total leucocyte count of 100,000, of these 95 per cent., or in all 95,000, may be lymphocytes, and the remaining 5,000 are polymorphs, with a few *eosinophils* and mast cells. In acute lymphatic leukæmia running a rapid course the larger immature type of cell predominates, but it is difficult, if not impossible, to distinguish these from myeloblasts in myeloblastic leukæmia. On the other hand, the total number of leucocytes per cubic millimetre may not be much, if at all, above the normal ; but if the total count of lymphocytes per cubic millimetre is increased, while the polymorphs are unaltered or diminished, the condition of lymphatic leukæmia must be recognised. Such cases are often called *aleukæmic leukæmia* ; this is indistinguishable from and probably identical with lymphosarcoma, since the histological picture of the lymph glands and of the blood is the same ; in fact, cases beginning as lymphosarcoma have terminated as lymphatic leukæmia. Usually there is a secondary anæmia with a few nucleated red cells. As in myelocytic leukæmia, there may be a megaloblastic reaction so that the picture of the red cells resembles pernicious anæmia.

Symptoms. *Acute lymphatic leukæmia.* This occurs in both sexes, and at all ages between seven and fifty-eight. The illness is fatal in from two weeks to three or four months. It begins insidiously with general weakness and malaise or pains in the spleen or joints. The external glands may enlarge, but are not always very prominent ; there is slight enlargement of the spleen and liver, and the bones may be tender. The marrow is packed with lymphocytes from the first and this leads to an early marked anæmia. A striking feature in many cases has been severe stomatitis with sloughing and gangrene of the gums ; and with this there are fever, and hæmorrhages from the gums and bowels and under the skin. Many of the solid glands in the body are densely packed with lymphocytes, and hence considerably enlarged, for instance the liver, spleen, kidneys, suprarenals, pancreas, salivary glands, and lachrymal glands, while the thymus persists and is greatly enlarged, and the cardiac muscle may be also infiltrated with lymphocytes. Exophthalmos has been also observed from leukæmic infiltration of the orbital fat. Dropsy occurs commonly before the end.

As contrasted with myelocytic leukæmia the spleen in lymphocytic leukæmia is rarely quite so large, and the lymphatic glands and organs all over the body, racemose as well as ductless, are often extensively involved.

Chronic Lymphocytic Leukæmia. This disease, which may last from about six months or a year up to twelve or even eighteen years, begins in the lymphatic glands, and involves one group after another, until all the lymphatic glands over the body may be affected, and they are felt in the neck, groins or axillæ. They are moderately large, not very hard, and move freely upon one another. The mesenteric glands are even more often enlarged than the above ; the retro-peritoneal, thoracic, portal, and iliac glands less so. On section the glands are whitish pink in colour, and microscopically are found to be distended with the lymphocytes. Later on, the bone marrow becomes involved, and is packed with lymphocytes, and this causes the onset of an aplastic anæmia. There is less tendency to hæmorrhage than in myelocytic leukæmia ; but patients may die

from the pressure effects of the glands on vital organs, or from their infiltration with lymphocytes or from venous thrombosis. In these chronic cases the spleen and liver may be very greatly enlarged.

Diagnosis. In any obscure illness with pallor, or enlarged glands, tonsils or spleen, or hæmorrhages, or purpura, or sloughing gums, the blood should be examined and the lymphocytes carefully estimated. The **Prognosis** is bad in the acute cases, in which there is little time for **Treatment** either by arsenic or by deep X-ray therapy. In less rapid cases these remedies should be tried.

Chloroma.—Presenting close relations with lymphatic leukæmia is the condition which has been called chloroma. In this there are numerous tumours or lymphoid deposits, especially in the orbits (so that exophthalmos may take place), in the temporal fossæ and in the periosteum of the bones of the skull. Tumours may also grow on the conjunctiva and under the skin, in various organs such as the kidneys, and sometimes even during life these tumours may have a green colour (*green cancer*), as seen through the skin; others are colourless (36). Cases of myeloid chloroma are rarer.

After death the various tumours are seen to have a green colour, which fades away on exposure; and the lymphatic glands, spleen, bone marrow, and other organs are in a condition similar to that accompanying lymphatic leukæmia. The nature of the green colour is not known; it is not bile pigment, but it is presumably the same as the green colour often noticed in pus.

POLYCYTHÆMIA RUBRA

Polycythæmia, or polycythæmia rubra, in which the red cells of the blood are increased, occurs (1) as a primary disease of the red cell-forming organs (*erythræmia*); (2) it also results from some disturbance in the circulatory or respiratory systems, causing oxygen want and requiring for compensation a larger number of carriers of hæmoglobin, such as in congenital heart disease. This secondary polycythæmia is called *erythrocytosis*.

Cases of polycythæmia rubra have an increased basal metabolism.

ERYTHRÆMIA

This occurs mostly in patients of between thirty and sixty years of age, though occasionally they are above or below these limits. In its pronounced form the red corpuscles vary in number from 9 and 10 to 13 and even 14 millions per cubic millimetre, and on standing the corpuscles may be found to occupy nine-tenths of the volume of the fluid. The hæmoglobin is raised to 130, 160 or 180 per cent. of the normal. The colour index is low, which shows that the red cells are small. The leucocytes are not always increased in number, but they may reach 24,000 per cubic millimetre, the chief increase being in the polymorphs. The viscosity of the blood is increased to three or four times the normal. The specific gravity and the coagulation time are not constantly either below or in excess of the normal. The blood pressure is sometimes, but not always, high.

Morbid Anatomy. The enlarged spleen is engorged, with hyperplasia of the splenic pulp and fibrosis, but generally without evidence of erythroblastic or myeloid activity. The lymph glands are generally unaffected: the liver may be engorged. The bone marrow is generally deep red in colour, and no fatty marrow is seen, so that there appears to be a great increase in the function of red corpuscle formation.

Pathology. In accordance with this, the generally accepted view of the pathology of the condition is that, from some cause or other, the bone marrow is stimulated to an excessive formation of erythrocytes, and that the other changes are secondary. There is no evidence that the polycythæmia is secondary to oxygen want in the tissues. Patients who are kept in an oxygen chamber show no alteration in the blood at the end of that time.

Symptoms. The conditions usually associated with this polycythæmia are *cyanosis* and a moderate or considerable enlargement of the spleen. The cyanosis is shown chiefly on the face, ears and mucous membranes (*see* Plate 36, A, p. 433). The face has a characteristic florid appearance; there may be jaundice and occasionally cirrhosis, the serum giving an indirect Van den Bergh reaction (38). The veins of the retina are engorged and very dark. The patients suffer from headache or a sense of fulness in the head, lassitude, vertigo, dyspepsia, constipation, thirst, and various forms of hæmorrhage, which include epistaxis, bleeding from the gums, menorrhagia, hæmatemesis and cerebral hæmorrhage. The arteries are sclerotic, leading to thrombo-angiitis obliterans, with intermittent claudication and erythromelalgia, or psychoses; the kidneys may be affected. There may be gout and renal calculi of uric acid (38). In some cases extensive venous thrombosis has occurred.

Differing somewhat from the above cases, which were first described as *polycythæmia with splenomegaly*, are some cases, less frequently occurring, in which the spleen is not enlarged, but the blood pressure is greatly increased, and may even reach 300 mm. Hg. The patients are often turgid in the face and may have hypertrophy of the heart, albumin in the urine, and signs of arterio-sclerosis. They were first described by Geisböck, who called them *polycythæmia hypertonica*.

The progress of cases of erythræmia is variable; death occurs from heart failure, or from cerebral vascular complications, or from tuberculosis.

Treatment. Periodic venesection is a good treatment for this disease. From $\frac{1}{2}$ to 1 pint of blood should be removed every six months through a wide hollow needle. Citrate may be used to prevent clotting, as in the withdrawal of blood for transfusion purposes. Success has also been obtained by treating the long bones by X-rays. Recently phenyl hydrazine 0.1 grm. per diem by mouth has been used.

ERYTHROCYTOSIS

Under this term it is proposed to include the cases in which the polycythæmia is again due to increased activity of the bone marrow (Parkes Weber), but this activity is stimulated by recognisable antecedent conditions. Thus one class is constituted by chronic cardiac and pulmonary lesions, of which congenital malformation of the heart is the most striking; and others are the various forms of acquired valvular disease, emphysema and chronic pulmonary diseases, which may be accompanied by cyanosis (Ayerza's disease, *q.v.*). In these the deficient oxygenation of the blood is the stimulus to the bone marrow. Patients who have been "gassed" form another group. Here the erythrocytosis has been lessened by treatment in an oxygen chamber containing 40 per cent. oxygen (Hunt and Dufton). Another group is formed by the polycythæmia of persons resident at high altitudes, where the increase of erythrocytes compensates for deficient oxygen tension in the air available for respiration. Polycythæmia also occurs in chronic poisoning by phosphorus and carbon monoxide and in Addison's disease and diabetic coma. As in erythræmia, the red corpuscles may reach seven, eight, or nine millions; the hæmoglobin and the viscosity of the blood are raised in amount.

HÆMOGLOBINÆMIA

Hæmoglobinæmia arises when blood corpuscles are broken up in the blood vessels, so that hæmoglobin escapes into the plasma, giving it a pink tinge, and the blood corpuscles have little tendency to form rouleaux. There is commonly anæmia with some poikilocytosis and anisocytosis; very pale corpuscles (*shadow corpuscles*) are seen. The hæmoglobin is excreted by the kidneys, so that the urine is coloured deep red and is *clear*; this condition is called *hæmoglobinuria*, and is distinguished from *hæmaturia*, in which blood itself with its corpuscles

is mixed with the urine, which is *smoky*, because light is reflected from the surfaces of the corpuscles. When examined by the spectroscope, the urine in hæmoglobinuria gives the two bands in the green and yellow characteristic of oxyhæmoglobin, and another band nearer the red end of the spectrum, which is due to methæmoglobin; the latter is produced by the action of the urine on the oxyhæmoglobin. The urine contains albumin. In slighter attacks probably only a small number of corpuscles are disintegrated, the hæmatin is disposed of in the liver, while the globulin alone is excreted in the urine; the protein found in the urine in such conditions is globulin and not serum albumin.

A partial destruction (*hæmolysis*) of the corpuscles takes place in several circumstances: (1) The action of certain poisons, such as chlorate of potassium in large doses, pyrogallie acid, arseniuretted hydrogen, and naphthol. (2) The transfusion of incompatible blood. (3) Exposure to extremes of temperature, such as burns or frost bite. (4) The action of some fevers, so that a moderate degree of hæmoglobinæmia may result from scarlet fever or typhoid fever. (5) In malaria or blackwater fever. (6) Paroxysmal hæmoglobinuria. (7) Very slight hæmolysis may be present in the blood of normal individuals.

PAROXYSMAL HÆMOGLOBINURIA

In this comparatively rare complaint hæmoglobinuria occurs in isolated attacks.

Ætiology. It is seen in young adults and middle-aged people up to fifty years of age, and is much more common in males than in females. In a few cases there is a history of malarial poisoning, and in very many a history of syphilis. The immediate cause of an attack is exposure to cold.

Pathology. The occurrence of the hæmolysis as a result of cold is explained as follows: there is a potential toxic *hæmolysin* in the blood of sufferers from this complaint, which as an amboceptor reacts with the corpuscle. The action of cold and subsequent co-operation of the complement with the return of warmth brings about destruction of the corpuscles. The complement exists in normal blood, and it has been shown that the patient's serum will hæmolyse normal corpuscles, hence proving that there need be no specific liability of the patient's corpuscles to break down. The toxic origin of the hæmolysin is suggested by the fact that in the majority of patients there is a history or evidence of syphilis, and a positive Wassermann reaction.

Symptoms. The beginning of the attack is marked in different cases by languor and weariness, a disposition to yawn, chill or rigor, pains in the limbs, nausea, vomiting, diarrhœa, and abdominal pain. The patients often suffer from Raynaud's disease (*see* p. 310), and in this case the fingers may become livid and cold.

The temperature may rise at the commencement, but soon subsides; and the duration of the symptoms is only from two to twelve hours. A slight enlargement of the liver and of the spleen is sometimes also observed. Either immediately after the first symptom, or after three or four hours, the blood-coloured urine is passed; but this condition is only of short duration: in a few hours more the urine may be perfectly clear, and free from albumin and hæmoglobin; and in the intervals between the attacks it is always perfectly normal. Towards the end of an attack an icteric tinge of the skin is observed; and after many attacks in quick succession the patient develops a microcytic anæmia. Paroxysmal hæmoglobinuria is not in itself dangerous.

Treatment. Exposure to cold must be carefully and systematically avoided by the use of warm clothing, residence in warm rooms, and protection from night air as far as possible. The syphilis should be treated chiefly with potassium iodide, mercury or bismuth. During the attack the patient should be kept in bed.

METHÆMOGLOBINÆMIA AND SULPHÆMOGLOBINÆMIA

(*Enterogenous Cyanosis, Microbic Cyanosis*)

A general lividity or cyanosis of the skin and mucous membranes is caused in rare cases by the conversion of the oxyhæmoglobin of the corpuscles into methæmoglobin and sulphæmoglobin.

Methæmoglobinæmia. This has happened from the use of certain drugs, especially acetanilide, phenacetin, antipyrin, veronal, and from the inhalation of poisonous fumes in workers dealing with coal-tar products, nitrobenzol, etc., and also from the absorption of nitrites in some intestinal lesions when diarrhœa is a prominent symptom, and when the production of nitrites may be due to organisms, as, *e.g.* the *Bacillus coli*. In some cases polycythæmia has been present, and sometimes enlargement of the spleen and clubbing of the fingers and toes. The patients have a ghastly chocolate colour. The blood shows no hæmolysis, but the corpuscles are very dark. There is usually no respiratory distress, because a marked colour is produced with a relatively small amount of hæmoglobin converted. The urine is generally normal. The **Treatment** is to remove the cause. Emetics and lavage may be required in poisoning by drugs. Since death is caused by deficient oxygen-carrying power of the blood, continuous oxygen administration, preferably with a tent, should be employed. After some hours the blood becomes normal spontaneously.

Sulphæmoglobinæmia. These patients, who are constipated, suffer from attacks of cyanosis, sometimes leading on to unconsciousness. Other symptoms in the attacks are headache, nausea and vomiting, and abdominal pain. The hæmoglobin in the corpuscles is partly converted into sulphæmoglobin. This substance resembles methæmoglobin in its absorption spectrum, a band being seen in the red. However, in the case of methæmoglobin this band disappears on adding a drop of 1 per cent. potassium cyanide, whereas in the case of sulphæmoglobin it remains unaltered. Another test is to pass acid-free CO through the mixture. All the bands of sulphæmoglobin are shifted towards the blue end of the spectrum. The bands of methæmoglobin are unaltered.

Like methæmoglobinæmia, the condition is due to poisoning with aniline derivatives, *e.g.* acetanilide and phenacetine, possibly associated with the formation of sulphur compounds in the gut due to constipation; but it may be a true enterogenous cyanosis, due entirely to poisons manufactured spontaneously in the gut, though this has been denied. It disappears much more slowly than methæmoglobinæmia, taking weeks or months. On this account if cyanosis follows medicinal doses of coal-tar drugs, it is almost certain to be sulphæmoglobin rather than methæmoglobin that is the cause. The simultaneous presence of both sulph- and methæmoglobinæmia in one patient has been described (23).

Prognosis. The disease is not fatal.

Treatment. Purges should be given for the constipation. Carious teeth should be removed. Oxygen should be administered continuously during the attack, especially if the patient is unconscious.

PURPURA

(*Hæmorrhagic Diathesis*)

This term is applied to a diseased condition in which a number of hæmorrhages occur under the skin or mucous membranes, so as to produce blotches of a less purple colour. It has been already seen that there are similar hæmorrhages in a number of diseases, for instance in scarlatina, measles, variola, typhus, cerebro-spinal fever, and plague; in cirrhosis, acute yellow atrophy of the liver, and leukæmia, aplastic anæmia, and malignant sarcomatous growths (*sarcoma-*

toxis) ; in malignant endocarditis, and other diseases of the heart ; and in some nervous diseases, *e.g.* tabes dorsalis. Hæmorrhages will be again mentioned in connection with hæmophilia, Hodgkin's disease, Bright's disease, and scurvy. As a direct result of poisoning from without, purpura arises from overdosing with potassium iodide, and from the commercial use (handling and inhalation) of benzol or its chief constituent, benzene. In all these cases it is clearly recognised that a cause for the hæmorrhage exists, and this cause is often an infective toxin or other poison.

Primary or idiopathic purpura has been divided clinically into different varieties : (a) *P. simplex*, *hæmorrhagica*, *fulminans* ; (b) *Henoch's purpura* and *Purpura rheumatica* (*Peliosis rheumatica* or *Schönlein's disease*), in which there is urticaria as well as purpura, and often the urticaria is more pronounced than the purpura (39) ; the term *anaphylactoid* purpura is sometimes used for this group.

Pathology. In severe cases of purpura a hæmolytic streptococcus can usually be isolated from the blood during the febrile period, and in fatal cases it can be cultivated from the heart's blood. The endothelium of the aorta is often stained with hæmoglobin pigment. These facts point to this organism as the cause of the disease ; its toxin may act by increasing the permeability of the capillaries so as to allow escape of plasma and diapedesis of red corpuscles into the tissues. Some purpuras result from *allergic* shock.

The blood shows the characters of a secondary anæmia if hæmorrhage is severe. The coagulation time of the first drop of blood taken from a prick is normal, but the coagulation time of subsequent drops is increased, being over a minute (2). It is possibly on account of this that the "bleeding time" (*see* p. 423) is increased. After the blood has clotted outside the body the clot does not retract and allow serum to ooze out (26, 29). The bone marrow does not show any characteristic changes ; if the demands on it are excessive and the nutrition is impaired by anæmia, it may become aplastic.

In the majority of purpuras of all kinds the blood platelets are absent or greatly diminished (*i.e.* under 100,000 per cubic millimetre (normal 200,000 to 500,000)) — a condition known as *thrombocytopenia*. This might at first sight be considered enough to account for the purpura. However, thrombocytopenia by itself is not sufficient, for in scurvy, where there are bleedings, and in Henoch's purpura, the platelets and bleeding times are both normal. The explanation probably is that the endothelial damage is the essential factor in all purpuras, and this may take place without diminution of platelets, but that since platelets and endothelial cells are closely related genetically the poison—whether it be anti-platelet serum, benzol, etc.—usually destroys the platelets before attacking the endothelium (22). If only enough anti-platelet serum to destroy the platelets is injected, no purpura follows, so that the thrombocytopenia cannot be the essential feature of the disease. Another suggestion, which, however, is not supported by experimental evidence, is that the platelets disappear because by agglutination they fill up the gaps in the bleeding vessels. Platelets are formed by the marrow and they are absent when the marrow is aplastic ; they are destroyed by the spleen, and its removal increases the number for a time, but only for a time.

Symptoms. In its mildest forms (*P. simplex*) purpura consists in the appearance of spots of a dull red, deep red, or bluish-purple colour in different parts of the body. They are circular, vary in diameter from a millimetre to $\frac{1}{2}$ inch, do not disappear on pressure, and are generally, when of this small size, not raised above the surface. They are scattered indiscriminately over the body. Each spot fades after a time, becoming brown or yellow in tint, and the larger patches go obviously through the changes characteristic of a bruise. Very little constitutional disturbance accompanies the eruption ; the patient may be pale, and loses appetite. Recovery generally takes place in from ten to twenty days.

In severe cases the hæmorrhages are more extensive, the skin may be raised by

large masses of blood beneath it, and bleeding takes place from the various mucous membranes (*P. hæmorrhagica*). The nose, mouth, stomach, and intestines, the kidneys, the female genital organs, and occasionally the bronchial mucous membrane may thus be the source of the blood. The gums are never swollen as in scurvy, but sometimes a spot of hæmorrhage is seen in their substance. In the severer cases there may be some rise of temperature, and a stage of prostration ensues which terminates in death. Post-mortem examination may reveal other ecchymoses in nearly all the mucous membranes, in the pelvis of the kidney, in the pleura, pericardium, peritoneum, in the meninges, and even in the lungs and the medulla of the bones. A cerebral hæmorrhage may be the cause of death. Sloughing and ulceration of the intestinal mucous membrane have also been found, leading to perforation and peritonitis. *Purpura fulminans* is the name given to some cases which are fatal in from five hours to three days. Many of these cases have occurred after scarlatina.

In *Henoch's purpura* the lesion of the skin, which may be erythematous or urticarial swellings, often of large extent, associated with but little hæmorrhage, is accompanied by joint pains and swellings, attacks of abdominal pain, vomiting and hæmorrhage from the bowel and hæmaturia. The spleen may just be palpable. It occurs in children, and recurs frequently during weeks or months. The sequence of symptoms in these cases varies a good deal, and the purpuric eruption is often late in its appearance, and not always very extensive; this fact may explain why there is no anæmia or thrombocytopenia. On the other hand, the early occurrence of the joint pains may give rise to a diagnosis of acute rheumatism, and in many instances the abdominal symptoms are the most prominent. Thus abdominal pain, vomiting, and distension sometimes suggest intestinal obstruction or appendicitis; or the same symptoms with hæmorrhage from the bowel and a palpable tumour occurring in a child lead to a diagnosis of intussusception. Laparotomy has been performed when the abdominal symptoms are present alone and the supposed intussusception has proved to be a portion of bowel infiltrated with effused blood. The urine may contain much albumin, with or without blood or casts, or pure blood. Many cases are fatal; others recover, but in them the albuminuria may persist for months. In *Purpura rheumatica*, which is probably a milder form of Henoch's purpura, the acute arthritis is prominent, associated with purpuric erythema and urticaria, and there may be endocarditis and pericarditis.

Diagnosis. In making the diagnosis, all the possible causes of a petechial eruption mentioned in the first paragraph must be excluded. *Scurvy* is distinguished by the spongy condition of the gums, the subcutaneous or fascial hæmorrhages. *Malignant sarcomatous* growths may present some resemblance to *P. hæmorrhagica*. It is well also to remember that the children of the poor sometimes present extensive petechial eruption as the result of *flea bites*, about the size of a pin's head. The sphygmomanometer provides a valuable test for the hæmorrhagic diathesis; a pressure just enough to obliterate the pulse is exerted on the arm for two minutes; if positive, purpura, often extensive, will appear on the forearm.

Treatment. Septic foci should be eradicated. In milder cases, rest in bed, tonic medicines, and good simple food will often rapidly effect a cure. When the purpura affects the lower extremities chiefly, it often disappears directly the patient takes to bed, and returns if walking about is too hastily resumed. Iron, arsenic, and quinine may be given in the usual doses. Intramuscular injections of calcium chloride (1 grain in 100 minims of water) or 3 c.c. calcium gluconate once a day may be of value; also an injection of 10 c.c. serum, preferably human, may be given, and this may be repeated. Liver treatment in thrombocytopenia, as given for pernicious anæmia, has been advocated (40).

In severe cases blood transfusion may be of value, and the spleen has been removed with beneficial results on the supposition that it is destroying the blood

platelets (27). It has recently been claimed that all cases do well with injections of ascorbic acid (*see* Scurvy), and if further experience bears this out it will be necessary to revise the views held as to the cause of purpura.

HÆMOPHILIA

Hæmophilia is a disease almost entirely restricted to the male sex, and characterised by a tendency to bleeding, either spontaneous or traumatic. It is hereditary. The disease is transmitted through the female, who is herself entirely free from it, and it only affects the male who is known as a "bleeder"; in this it resembles pseudo-hypertrophic muscular paralysis.

Pathology. There is delayed coagulation time of the blood, which may be increased to forty minutes or more. Consequently there is nothing to stop any small hæmorrhage that may occur accidentally. There is a very slow formation of pro-thrombin, although the platelets which form pro-thrombin are present in normal numbers and their agglutination is also normal. Thrombokinese, the other precursor of fibrin ferment, is also present in sufficient quantity (2), but the conversion of pro-thrombin into fibrin ferment is also very slow. If a state of anaphylaxis is induced the coagulation time is much shortened, and this has been made use of in treatment. The fatty degeneration of the heart and of the arteries found in some cases is probably the result of secondary anæmia. Certain other conditions must be distinguished from hæmophilia—an acquired form connected with syphilis, shortage of fibrinogen, hæmophilia calcipriva with a low blood calcium and essential thrombocytopenia (42). These conditions may account for the female "bleeders" which are occasionally met with (24).

Symptoms. These generally appear within the first year of life, though they are sometimes delayed till the seventh or eighth year. In the most severe degree, spontaneous hæmorrhages occur from the nose, the gums, and the mouth, and less commonly from the stomach, the lungs, or the genitalia; they are sometimes preceded by a feeling of fulness. Alarming and even fatal hæmorrhages may occur after the most trivial operation, such as vaccination, the extraction of a tooth, incision of an abscess, or after a cut finger. Besides these losses, hæmorrhage takes place readily under the skin from slight blows, producing bruises or blood tumours. Hæmorrhage also takes place into the synovial cavity of the joints, especially the knee joint; this occurs most commonly between the ages of seven and fourteen, and results from blows, or from exposure to cold or to damp. The swelling and pain closely resemble those of rheumatism or synovitis, for which, indeed, the symptom has been mistaken. This condition of the joint is accompanied by fever; it may recover, but returns again and again. Eventually the joint may become ankylosed or fixed by periarticular adhesions. A rheumatic affection of the muscles and the occurrence of trigeminal neuralgia are described as occasional complications of hæmophilia.

In the intervals between the bleedings the subjects of hæmophilia may appear to be in perfectly good health, but the loss of blood may cause anæmia. They may die from loss of blood before they are eight years of age; and though the chances of survival are greater after this period, even in middle age death may occur in the same way.

Diagnosis. This depends on finding an increased coagulation time of the blood.

Treatment. For a surface hæmorrhage the best treatment is to apply to the bleeding spot, cotton wool soaked in some fresh human blood after useless clots have been wiped away; but fresh animal tissue may also be used. The most certain method is to ~~give an injection of~~ snake venom, but a transfusion of citrated blood lowers the coagulation time for a period of five to seven days. It has, in fact, been stated that every hæmophilic should be tested against five or six possible donors, so that one of them at least would always be available in a

sudden emergency. It is not necessary to use much blood. Alternately citrated human plasma should be transfused: in this case blood grouping is not necessary. In case an operation becomes necessary a preliminary transfusion should be carried out, and this preparation is advisable before even the smallest operation, *e.g.* the extraction of a tooth. An injection of 10 c.c. horse serum ten days previously to produce anaphylaxis is much less certain (41). Some shortening of the coagulation time may be brought about by giving a diet of liver as for pernicious anæmia (42). When the albumin globulin ratio of the plasma is low (normal 4 to 1) injections of ascorbic acid (*see* Scurvy), 200 mg. for an adult, 100 mg. for a child, have been successful (43).

For the stiff joints hot-air baths and gentle massage may be employed: breaking down the adhesions under an anæsthetic is generally avoided, from fear of starting a fresh hæmorrhage, but it has been done without this accident following. Considering the serious nature of this disease and the manner in which transmission takes place through the female sex, it is clear that women who belong to bleeder families, even though themselves not the subjects of hæmophilia, should not marry.

BLOOD TRANSFUSION

By this term is meant the taking of blood from a healthy person ("the donor") and injecting it into the circulation of a patient ("the recipient") for therapeutic reasons. The indications for this treatment in medicine are—(1) simple hæmorrhage, *e.g.* in gastric and duodenal ulcer, dysentery, typhoid, ectopic gestation, melæna neonatorum; (2) diseases of the blood, *e.g.* severe purpura, hæmophilia, anæmia, leukæmia; (3) severe infections, *e.g.* infective endocarditis; (4) possibly certain intoxications, such as threatening uræmia.

Methods which necessitate cutting down on the artery or vein of the donor are undesirable, owing to the slight, but definite, risk to the donor from sepsis. The donor runs no risk if the blood is taken through a wide, hollow needle plunged directly into the median basilic vein; the point of the needle should be sharpened on an Arkansas stone and examined with a lens or low power of the microscope. In the "citrate method" the blood is run from the needle through a short piece of rubber tubing into a sterile measuring vessel containing 160 c.c. 3·8 per cent. sodium citrate solution (made with freshly distilled water) to 700 c.c. of the blood. The rate of flow is increased by means of pressure round the arm above. The blood must be kept warm all the time. A sterile cylindrical funnel, containing a little saline, and fitted with a rubber tube and clip and needle, is used for the infusion. A short piece of glass tube is inserted close to the needle to act as a window, and to make sure that the needle is in position the funnel is momentarily lowered until blood enters the glass tube; it is then raised and filled with the citrated blood. A sterile bottle may also be used so that the blood can be removed from the donor by suction and administered under slight pressure to the patient. If the donor becomes faint or pale or sweats, or if the pulse falls below sixty, the withdrawal of blood must be stopped. Favourable results have been obtained, especially in infections, by the use of defibrinated blood, which appears to retain its antitoxic or antibacterial properties to a greater extent than citrated blood. Instead of adding citrate the blood is agitated as it flows into the bottle and the fibrin becomes deposited on a bent glass tube which passes down from the stopper to the bottom of the bottle, and up again. Before injecting the blood it must be filtered through sterile gauze to remove small tags of fibrin. In "immuno-transfusion" the donor is immunised beforehand, or the blood is immunised *in vitro*.

Certain precautions must be taken. The Wassermann reaction of the donor should be investigated, and the "compatibility" of the bloods of donor and recipient must be determined.

Compatibility. It is sufficient if the donor's cells are not agglutinated by the recipient's serum. The reverse condition need not hold, because the donor's serum rapidly becomes diluted in the circulation of the recipient. To test compatibility a drop of blood from the donor's finger is allowed to fall into 1 c.c. of 1.5 per cent. sodium citrate solution, and one drop of the resulting suspension is mixed on a microscope slide with one drop of the recipient's serum and covered with a cover slip. After the lapse of a few minutes the slide is examined macroscopically for agglutination. Individuals are arranged in four groups, thus :—

		Serum			
		Gr. I.	Gr. II.	Gr. III.	Gr. IV.
Cells	Gr. I.	—	+	+	+
	Gr. II.	—	—	+	+
	Gr. III.	—	+	—	+
	Gr. IV.	—	—	—	—

It will thus be seen that, if the sera of groups II. and III. are kept in stock, the cells of any given individual can be assigned to their group. The cells of group IV. are agglutinated by no one, and, therefore, the members of group IV. can always act as donors, but it is generally safer to have both donor and recipient of the same group. It has been pointed out that a time control test is advisable ; the recipient's serum is mixed with cells from a blood of known incompatibility, and the time taken for agglutination is noted ; this has been as long as half an hour and the test with the donor's cells must be watched for the same length of time ; by this means the death-rate, 1-2 per 1,000 transfusions with apparently compatible blood may be lowered (44).

REACTION OF THE BLOOD AND ACIDOSIS

The reaction of any solution depends on its concentration of hydrogen ions (C_H) and hydroxyl ions (C_{OH}). When the reaction is neutral, the concentration of hydrogen and hydroxyl ions is equal ; when it is acid, the C_H is increased and the C_{OH} is diminished ; when it is alkaline, the C_H is diminished and the C_{OH} increased. The product of the two is always constant. At the neutral point and at body temperature the C_H , expressed in grams of hydrogen per litre, is 1.83×10^{-7} , which is the same as $10^{-6.74}$. The C_H of the arterial blood is about $10^{-7.40}$, which, being smaller than $10^{-6.74}$, is slightly on the alkaline side of neutrality. The method usually adopted of expressing these facts is to say that at the neutral point p_H (the logarithm of C_H) is 6.74, leaving out the minus sign for the sake of simplicity.

The C_H of blood is given by the equation

$$C_H = \text{constant} \times \frac{\text{CO}_2 \text{ pressure}}{\text{bicarbonate concentration.}}$$

the CO_2 pressure being proportional to the CO_2 dissolved in the blood. In normal people the CO_2 pressure of the arterial blood is just below the CO_2 pressure in the alveoli of the lungs. The variations in this equation can best be seen from the following table : (45)—

TABLE I.—Types of Disturbance of Acid-base Balance

(1) Affecting CO_2	(2) Affecting Bicarbonate Concentration
(a) <i>Increase.</i> Increased formation — violent exercise. Impaired elimination. Depression of respiratory centre by narcotics, and sleep. Interference with respiration (disease of heart or lungs). Breathing CO_2 .	(a) <i>Decrease.</i> Excessive ingestion of acids, or potential acids (NH_4Cl or CaCl_2).
(b) <i>Decrease.</i> Overbreathing—voluntary, in hysteria, emotional tetany, as a result of peripheral stimuli, in fevers, at high altitudes, in pure cardiac dyspnoea.	Excessive formation of acids—lactic acid in exercise.
	Failure of oxidation of acids—especially aceto-acetic acid.
	Failure of excretion of acids in nephritis.
	Loss of base.
	(b) <i>Increase.</i> Excessive ingestion of bases (NaHCO_3) or potential bases (e.g. sodium citrate).
	Loss of acid, e.g. gastro-colic fistula.

If the CO_2 pressure rises out of proportion to the bicarbonate, the C_H will be increased; in other words, the blood will be abnormally acid; this results from the conditions in 1 (a), and is known as *acidæmia*. The same thing results from a decrease in the bicarbonate concentration as shown in 2 (a). The term *alkalæmia* is used for the opposite condition, when the C_H is abnormally diminished; this occurs from a diminution in the CO_2 as shown in 1 (b) or an increase in the bicarbonate as shown in 2 (b). There is mild alkalæmia at high altitudes, and after washing out CO_2 from the body by forced breathing (acapnia) (1, b) and it is sometimes associated with tetany (see p. 488); it occurs after taking large doses of alkali (2, b) which also causes a lowered sugar tolerance and ketosis.

While the concentration of CO_2 depends on the respiration, the concentration of the bicarbonate ion is the resultant of all the non-volatile acid and basic substances of the blood. Among the acid substances of importance are oxyhæmoglobin and various acids which are produced in metabolism, such as chloride, phosphate, sulphate and abnormal acids like β -oxybutyric and aceto-acetic acids, while the basic substances are oxides of sodium, potassium, calcium and magnesium. The bicarbonate, the resultant of these acids and bases, is measured by the amount of CO_2 in the blood at a fixed pressure of CO_2 , viz., 40 mm. This is defined as the *alkali reserve* of the blood, the *fixed CO_2* , or the *blood bicarbonate*. The normal value lies between 40 and 54 c.c. per 100 c.c. of blood at 38°C .

The term *acidosis* was first of all introduced to indicate the production of aceto-acetic and β -oxybutyric acids in the body and their excretion in the urine in diabetes, the condition which is now called *ketosis*. More lately *acidosis* has been used as equivalent to diminution in alkali reserve or blood bicarbonate, in whatever way this has been brought about. Other authors, however, have used the term to mean increase in the C_H of the blood, a totally different thing. Owing to this confusion in terminology, it is best to use the term *acidosis* to indicate the process of acid production in the body and *alkalosis* to indicate the process of alkali production.

The foregoing remarks are important when the cause of certain common types of dyspnoea is considered. In emphysema, asthma and bronchitis, and bronchial obstructions due to growths, when these conditions are associated with dyspnoea, there is marked acidæmia, owing to accumulation of CO_2 in the blood (1, a, in the table). In such cases, owing to the condition of the lungs, the CO_2 fails to escape in spite of the increased breathing. Want of oxygen may also play a part in the dyspnoea of some of these cases. The alkali reserve of the blood may remain about normal, though it is often raised considerably by the diffusion of bases into the blood from the tissues.

In the dyspnoea of mitral disease, the CO_2 is lowered from increased respiration

and there is alkalæmia (1, *b*). The alkali reserve is normal, provided there is no very extensive generalised œdema. In the latter case it may be diminished.

Acidæmia may be present in other conditions of clinical importance: ketosis, chronic or "asthenic" uræmia, and eclampsia. In ketosis the accumulation of aceto-acetic and β -oxybutyric acids in the blood is the primary cause of the acidæmia. They stimulate the respiratory centre, so that the respiration is increased and CO_2 is washed out of the blood, with lowering of the alkali reserve; but the CO_2 is not diminished in proportion, so that some rise in the C_{H} can be measured quite in the early stages. In the later stages, towards the onset of coma, a very considerable degree of acidæmia may occur (2, *a*). Ketosis will be considered further in the section on diabetes. The acidæmia of uræmia, œdematous nephritis, nephritis and eclampsia is also due to accumulation of fixed acids—the phosphate and sulphate ions in particular. In a case of uræmic coma (2, *a*) the p_{H} was 7.27 shortly before death. In a case of emphysema with CO_2 retention (1, *a*) the p_{H} was 7.24 some weeks before death, when the patient was walking about perfectly conscious. It is thus very doubtful whether the acidæmia by itself is the cause of uræmic coma, since the blood of the emphysematous patient was more acid. Coma is more probably due to the poisonous character of the acid substances retained in the blood. The same theory may apply in ketosis, for in this condition there is good evidence from the structure of its molecule that aceto-acetic acid is itself a poison (Hurtley and Trevan). In normal pregnancy and in secondary contracted kidney long before uræmia supervenes, there is a measurable lowering of the alkali reserve. In polycythæmia and in gas gangrene the alkali reserve is also lowered, and probably also in various febrile conditions.

The alkali reserve is increased and there is alkalæmia if hydrochloric acid is lost from the stomach by vomiting or through gastro-colic fistula (2, *b*); in some cases there is a secondary ketosis as there is after ingestion of alkalies and in spite of the alkalæmia the urine remains acid (37) owing to loss of salt (47).

There are various mechanisms for keeping the C_{H} of the blood within comparatively narrow limits. Acid is excreted by the kidney in two ways: (*a*) the urine is made more acid than the blood by the predominance of acid over basic phosphate; (*b*) ammonia is formed, and this combines with the acids to form neutral salts, which are excreted. The ammonia of the urine is thus increased. (*c*) Alkali is also excreted through the kidney; this takes place in pure cardiac dyspnoea or at high altitudes, when the CO_2 pressure is reduced by over-breathing (1, *b*); the loss of alkali by the kidneys then reduces the alkalæmia by lowering the alkali reserve. (*d*) The "buffer" action of the alkali reserve in preventing changes of C_{H} is helped by the tissues which have the power of taking up or giving out fixed acids and bases or even of manufacturing fixed acids, *e.g.* ketone bodies after alkali ingestion.

Diagnosis. Breathlessness is a valuable indication of acidæmia; but this may be due to (*a*) want of oxygen, (*b*) reflex action, as is possibly the case in primary heart disease, where the respiratory pump helps the circulation, (*c*) local irritation of the respiratory centre, (*d*) acidæmia, increase of CO_2 or fixed acid in the blood. (*a*) The patient will probably show lividity or cyanosis. (*b*) The respiration is rapid, and there will be evidence of heart disease. (*c*) There will be evidence of intra-cranial disease, such as cerebral hæmorrhage, and the patient will probably be unconscious. (*d*) Where there is no primary lung lesion, which causes acidæmia by increase of CO_2 , the increased respiration will probably be due to increase of fixed acid in the blood. The respirations are often slow and deep. The most accurate measure of the amount of fixed acid is to determine the alkali reserve directly, but this is hardly a clinical method. Three other methods may be used: (1) The ratio of the ammonia nitrogen to the total nitrogen in a specimen of urine may be estimated. Normally this is 3 to 5 per cent. In severe cases of acidæmia values of 20 to 40 per cent. may be obtained.

(2) The alveolar CO_2 may be measured by some apparatus, *e.g.* Fridericia's CO_2 tensimeter, a determination taking about ten minutes. (3) The amount of sodium bicarbonate which is required, when given by mouth, to make the urine alkaline to litmus, may be determined. Five grammes are enough for this in normal people. When the alkali reserve is diminished a larger amount will be necessary, and gradually increasing doses at three or four hourly intervals may be given to test this (Sellards).

It is very necessary to make a sharp distinction between ketosis where the nature of the fixed acids is known and other conditions of lowered alkali reserve and acidæmia. Ketosis can readily be diagnosed by the mahogany brown colour of the urine when ferric chloride is added to it and the purple colour with Rothera's or Legal's tests, and by the smell of acetone in the breath. The presence of ketosis is not always due to lack of available carbohydrate in the body, tending to acidæmia. It is produced by giving large doses of sodium bicarbonate, which tends to alkalkæmia.

Treatment. It has already been stated that it is doubtful how far acidæmia itself is a cause of death; but when it is present accompanied by a lowered alkali reserve, it is reasonable, in the present state of our knowledge, to counteract it. For this purpose sodium bicarbonate or sodium citrate may be given in drachm doses by the mouth every two hours. In acute cases an intravenous injection of 2 per cent. sterilised sodium bicarbonate may be given.

Where it is believed that the clinical condition is due to poisons in the blood the formation of the latter must be arrested (*see* under Ketosis), and their excretion must be facilitated. (*See* Treatment of Diabetic Coma.)

DISEASES OF THE SPLEEN

The spleen lies in the upper part of the abdomen on the left side, and is entirely concealed by the ribs. In health its position and size can only be estimated by percussion. There is dulness in the left infra-axillary region over the ninth, tenth, and eleventh ribs, and the included spaces. In front, this dulness is limited by a line drawn from the left nipple to the tip of the eleventh rib; behind, it reaches nearly to a line continuous with the anterior margin of the latissimus dorsi. If the spleen becomes enlarged, it extends downwards and forwards, and if the fingers be placed under the ninth and tenth costal cartilages while the patient takes a deep breath, the margin of the spleen can be felt to impinge against them. With greater enlargement, it comes distinctly below the ribs at this point, so that it can be readily felt, and occupies more or less of the left upper quarter of the abdomen. In extreme cases the spleen reaches down to Poupart's ligament and crosses the middle line below the umbilicus, though it may remain on the left side above. An enlarged spleen is always dull when percussed through the anterior abdominal wall; it comes from immediately behind the lower ribs, remaining in contact with the anterior abdominal wall. Its edge is sometimes felt projecting from under the ribs, further back in the loin. The anterior margin often presents one or two distinct notches. If the enlargement is very considerable there may be a dragging sensation or feeling of weight in the left side. Pain may be present from the formation of infarcts, and from the resulting perisplenitis, but is not a marked feature in the enlargements which accompany fevers. For X-ray examination of the spleen, *see* p. 383.

Histologically, the spleen has a lobular arrangement, and its arterial supply passes either to (1) the Malpighian corpuscles, which are merely small lymph glands, or (2) to venous sinuses, and so on to the veins, or (3) the pulp, and then through pores in the walls directly into the veins; before entering the venous sinuses or the pulp the blood passes through *ellipsoids*, bodies situated on the arterioles, which probably have the function, among others, of acting as valves

preventing blood from passing back into the arterial system from the pulp or venous sinuses. The pulp consists of a reticulated network on which lie branching multipolar cells and large amœboid phagocytic cells; these three elements constitute the *reticulo-endothelial* system.

Important functions of the spleen are the phagocytosis of foreign substances in the blood and the destruction of worn-out blood corpuscles, but the spleen also acts as a regulator of the blood volume, turning out blood from the pulp into the splenic veins and so into the circulation as occasion requires. Thus it may shrink to one-fourth or one-sixth of its normal size during hæmorrhage, or during exercise or exposure to heat, when extra blood is required in the skin for cooling purposes or during asphyxia (25). In disease the size of the spleen is very variable, probably owing to this regulating function.

The pathological changes to which the spleen is liable will now be summarised; their symptomatology and treatment are dealt with elsewhere.

Active Congestion. The spleen is enlarged in many acute infectious processes, and this is most prominently the case in enteric fever, in relapsing fever, in ague and other malarial fevers, in pneumonia, pyæmia, malignant endocarditis, purpura, phthisis, and acute tuberculosis, and less so in puerperal fever, erysipelas and syphilis. The capillaries and veins are distended with blood. The splenic pulp is swollen, and the capsule of the organ is distended. After death the spleen is found to be of dark red or purple colour, and very soft; and the pulp is readily washed away by a current of water. The histological changes resulting from infective processes in the spleen are, according to Muir, as follows: great phagocytic activity of the cells of the pulp, especially non-granular hyaline cells and endothelial cells, which may be seen to contain numerous red cells, and neutrophil leucocytes; the presence of myelocytes in the pulp; apparent enlargement of the Malpighian corpuscles due to proliferation of cells around them.

Splenitis and Perisplenitis. In some of these infective conditions the process goes beyond the stage of hyperæmia into one of acute inflammation, as shown, according to Ziegler, by the excessive quantity of white cells found within the vessels and pulp. Abscess is a very rare result of general splenitis. Accompanying the splenitis there may be inflammation of the capsule, *capsulitis*, or *perisplenitis*, with resulting adhesions to adjacent organs, or to the abdominal parietes. Acute or chronic capsulitis is very frequently found at post-mortem examinations; and its occurrence can often be traced, especially in the acute form, to infective processes.

Embolic Infarcts. These are the results of the impaction of fibrinous particles, detached from the valves of the heart or from thrombi in its cavities. The infarcts form wedge-shaped or conical masses, which may reach a large size, and occupy one-half or two-thirds of the organ; these are a cause of splenomegaly. They go through the changes of colour elsewhere described (*see* p. 313), and in septic cases they may become purulent. Infarcts also occur in the spleens of leukæmia and splenic anæmia.

Tubercle. This appears in the spleen as a part of general tuberculosis, in the form of grey or often bright yellow nodules, which may reach the size of small peas, scattered throughout the substance and on the surface. Sometimes large yellow caseous masses up to an inch in diameter are found, and these may cause splenomegaly.

Other Causes of Chronic Enlargement. A moderate enlargement is seen in malaria, rickets, congenital syphilis, Hodgkin's disease, erythræmia and lardaceous disease (*see* p. 399); *Syphilitic* gumma is rare, but the greatest size is reached in leukæmia, especially the Gaucher variety, in infantile pseudo-leukæmic anæmia, in splenomegalic cirrhosis, in Kala-azar and in Egyptian splenomegaly, in all of which the organ may occupy a large part of the abdomen. Hydatid cyst and old blood cysts resulting from hæmorrhage occasionally cause splenomegaly. Finally there is a varied group of large spleens, associated with

involving those of the axilla and the groin. The glands form irregular and nodulated masses of different sizes, as large as a pigeon's or hen's egg, and are usually firm, painless, and at first freely movable upon one another under the skin. Subsequently they may become adherent, but rarely suppurate. The mediastinal glands are affected as shown by X-rays, and sometimes a broadening of the mediastinal shadow is the first evidence of the disease (Plate 15B, p. 308.) The mesenteric and retro-peritoneal glands are also affected. In many of these regions the growth of the glands may be such as to cause serious pressure on the neighbouring parts. These are—in the neck, the larynx, trachea, and œsophagus; in the thorax, the large veins and the recurrent laryngeal nerves. Occasionally the bones are invaded, but they do not fracture as they are liable to do when they are invaded by carcinoma; paraplegia may follow from pressure on the cord, or without obvious cause.

The *spleen* is, as a rule, only moderately enlarged; it projects a little below the left costal margin, or occupies the left upper quarter of the abdomen; it rarely attains the same size as that seen in myelocytic leukæmia. Secondary *anæmia* is a comparatively early prominent symptom; and in severe cases poikilocytes and nucleated red cells are seen. The leucocytes are increased in number, and when the glands are softer than usual amount to as many as 15,000 or 20,000 per cubic millimetre. But usually the increase is but slight. It is due to an increase in the polymorphs, which are commonly above 5,000 per c.mm. (see p. 427), and this is a valuable diagnostic point; but there is sometimes a leucopenia. *Pigmentation of the skin* sometimes occurs, and may be due to interference with the function of the adrenal cortex; occasionally there is intense *pruritus*, with *prurigo*, and this may suggest the diagnosis, also *herpes* and *lymphadenomatous* infiltration of the skin.

Pyrexia. When the deep glands are involved there may be a relapsing pyrexia (see Fig. 55), which differs from other "relapsing" fevers in the greater length of the span, which in 85 per cent. of cases lies between fifteen and twenty-five days, and is fairly constant for each individual case (28 (*Pel-Ebstein's disease*)). There may also be continuous pyrexia.

A certain amount of weakness is soon observed, and as the disease progresses the effects of the anæmia become more pronounced. There may be dyspnoea. In time, also, œdema of the lower extremities takes place with, perhaps, ascites, pericardial effusion or hydrothorax; and hæmorrhage from the nose or gums, or under the skin, may occur as in other severe blood diseases. The deposits may ulcerate through the skin. Finally, death is caused by exhaustion, suffocation, hæmorrhage, coma or convulsions, or by pneumonia, pleurisy, or œdema of the lungs.

Diagnosis. It may be difficult to distinguish the early stage of Hodgkin's disease of the glands from tuberculous enlargement, especially when the growth is confined to one set of glands. However, tuberculous glands tend to be matted together; in Hodgkin's disease the glands are usually discrete. Tubercle usually affects one group of glands; in Hodgkin's disease the changes are eventually widespread. The glandular enlargement from neoplasm and glandular fever must be distinguished; in the latter there is a mononucleosis, and in Hodgkin's disease, as already stated, a polymorphonuclear leucocytosis. X-ray examination of the chest and Gordon's biological test have also been mentioned. A relapsing temperature of the kind described is a strong point in favour of Hodgkin's disease.

Prognosis and Treatment. Arsenic has been of great benefit in some cases; it should be given in increasing doses until as much as 15 minims of the liquor arsenicalis three times daily is being taken. Arsenobenzol and novarsenobenzol are also valuable. Good results have been obtained by means of deep X-ray therapy; the immediate results are good and deposits disappear to begin with. Whereas patients lived a few months previously, they now live for a few years. Vaccine therapy with Gordon's virus is still in the experimental stage.

is prevalent among the Jews. It may be hereditary, or may occur in brothers and sisters of the same family. Hereditary diabetes may be very mild, but often shows a tendency to become more serious and to begin at an earlier age in successive generations. Diabetes often attacks fat people who eat plenty and take little exercise. Hence it is especially a disease of the well-to-do. This fact may be explained by the increased metabolism that follows excessive eating, which makes greater demands on the pancreas and other organs. The association of diabetes with gout is also probably explained by both diseases occurring in overfed people. In the Central Empires war diet had a profound influence on the disease, causing the glycosuria of fat elderly people to disappear. This fact had been observed by Bouchardat during the siege of Paris. Probably the most important factor was the reduction of the meat ration. There is a very general impression that diabetes is apt to occur in people who eat sugar and sweets to excess, but this lacks statistical proof. The great prevalence of a mild form of diabetes in India is probably associated with obesity, to which the excessive carbohydrate diet and the lack of exercise contribute. A strenuous life, nervous strain and emotional shock may play a pronounced part in the onset of the disease. This is of special interest owing to Cannon's observations that emotion in animals caused hyperglycæmia from excitation of the suprarenals, and that students who were up for examinations, or about to undergo some important physical test, such as playing for their college, often had glycosuria. Graham found in his own case that the blood sugar rose to 0.15 per cent. thirty minutes after taking 100 grammes of dextrose, but that when the same test was carried out after a period of hard work, when he was in need of a holiday, the value was 0.185 per cent., and this persisted for half an hour. True diabetes has followed exophthalmic goitre. Acute infection is a predisposing cause, whether this is general or localised particularly to the neighbourhood of the pancreas, giving rise to a pancreatitis. The diminished sugar tolerance and glycosuria found in septic conditions, sometimes called *sapraemic* glycosuria, must also be mentioned. The glycosuria disappears with relief of the condition. Syphilis is also a possible cause. Diabetes of a mild kind is common in the later decades of life. It is possible that atheroma or senile arterial changes or diffuse hyperplastic sclerosis may lead to some defect in the islands of Langerhans, similar to the slight defect in excretory power that may accompany arterio-sclerotic kidney. In diabetic gangrene both the diabetes and the gangrene may have a primary vascular cause; but the gangrene undoubtedly increases the glycosuria, which often clears up after operation. The reverse also holds, since the gangrene may clear up with insulin. Diabetes has followed trauma, not only over the site of the pancreas, but in places far removed, *e.g.* a fractured limb. Head injuries may cause glycosuria; these are probably analogous to Claude Bernard's "puncture diabetes" (*see later*).

Physiology of Carbohydrate Metabolism. The carbohydrate reserves of the body are stored in the form of *glycogen*, which is about equally divided between the liver on the one hand and the muscles on the other. Glycogen is formed from the carbohydrates and proteins of the food. The latter are absorbed from the intestine in the form of amino-acids, which may be used to synthesise the proteins proper to the organism, or after deamination may be oxidised at once, or built up into glycogen. Carbohydrates are also broken down by digestion, and may be absorbed in the form of *dextrins* and of comparatively simple substances like *dextrose* and *lævulose*. These bodies all pass to the liver by the portal vein. The dextrins and lævulose are entirely taken up by the liver and formed into glycogen there. If very large amounts of lævulose are eaten some of it manages to get through the liver into the general circulation, and is then promptly excreted by the kidney, producing *lævulosuria*. This condition also occurs in disease of the liver, which under these circumstances is unable to hold back the amount of lævulose, which normally can be dealt with quite readily.

Dextrose *may* be partly kept back by the liver, but some of it certainly gets through into the general circulation, because the amount of sugar in the blood of a healthy person shows an increase immediately after a meal (*see* Fig. 57). The systemic blood is thus supplied with dextrose from two sources: (1) the food, which forms a variable supply; (2) the glycogen of the liver, which probably forms a fairly constant supply, the glycogen being broken down by an amylolytic ferment there. Before breakfast the concentration of dextrose in the blood usually lies between about 0.08 and 0.10 per cent. This constancy is preserved by means of a steady production of dextrose from the liver on the one hand, and its disappearance into the tissues on the other hand, where it is either oxidised to form CO_2 and water, or elaborated into more complicated compounds, one of these being the glycogen of the muscles.

Insulin, which is the hormone secreted by the islands of Langerhans, plays an essential part in these processes, though its action is complicated. It is best regarded from two points of view: (1) In the *periphery* insulin causes the disappearance of dextrose from the blood stream, since if administered to a diabetic the percentage of sugar in the venous blood of the arm is found to be less than the percentage in the arterial blood, whereas before administration the two values are nearly the same (5). The sugar that disappears is partly oxidised by the muscles, skeletal and cardiac, and partly built up into glycogen in the muscles (6) and probably changed towards fat. (2) Its *central* or *visceral* action is manifested on the liver in two ways: (a) In acute diabetes there is lipæmia and increase of fat in the liver, probably because, in default of carbohydrate, fat is mobilised from the dépôts and assembled in the liver to be utilised (7). Here it is probably converted into carbohydrate, which explains the low respiratory quotient found in severe cases, and this conversion involves the production of aceto-acetic and β -oxybutyric acid (*ketosis*) (8). Insulin arrests this process, the ketosis and lipæmia vanish, and the fat disappears from the liver, and the respiratory quotient rises. (b) The diabetic liver contains less glycogen than normal, since this is discharged into the blood and causes the well-known hyperglycæmia. It is not uncommon to find a concentration of 0.4 or 0.6 per cent. dextrose in the blood in severe diabetes. Insulin causes in the liver a retention of glycogen, which increases *pari passu* with the diminution in the liver fat. This result is possibly obtained because the insulin inhibits the action of the amylolytic ferment of the liver, which becomes excessive in its absence. The sudden fall in blood sugar, which is the most striking clinical effect of insulin, is thus due partly—probably only slightly—to oxidation and partly to storage in the muscles and to the fact that the excessive supply of sugar from the liver is stopped. At the same time any carbohydrate that is taken as food is partly stored in the liver as glycogen and probably partly converted into fat; the reason for the latter statement is that several observers have found a rise in respiratory quotient without any marked increase of combustion, which would occur if most of the sugar taken had been burnt. The following observation shows that storage of sugar by means of insulin may be only a temporary matter. A patient was given by mistake the enormous single dose of 100 units of insulin, and to counteract this was given by mouth immediately 110 grammes of carbohydrate in the form of dextrose and bread. This was retained in the tissues for two days and then largely excreted in the urine after the effect of the insulin had worn off (9).

The early stage of pancreatic deficiency, in which dextrans and amylolytic ferment enter the blood from the liver, is mentioned elsewhere (*see* p. 409). Three other ductless glands, the suprarenals, thyroid and pituitary act in the opposite direction to the islands of Langerhans, since their excitation increases the sugar in the blood. The suprarenals pour adrenin into the circulation, and this travels to the liver and causes the breakdown of glycogen into dextrose. For this action to occur it appears to be essential for the hepatic plexus to be intact. The thyroid probably acts by exciting the suprarenals. Claude

changes ; in healthy persons after taking large doses of sodium bicarbonate ; and in diabetes mellitus. When the aceto-acetic acid reaches a high concentration in the blood it may cause death by producing coma. This may occur in severe diabetes or after prolonged vomiting (*see* p. 341). In a very prolonged case of severe diabetes the body fat largely disappears as the patient wastes, and the ketosis may almost vanish, while the patient dies of inanition.

Clinical Tests for Ketosis. There is no colour test for β -oxybutyric acid in the urine. Gerhard's test, which is used for aceto-acetic acid, consists in adding ferric chloride to the urine when a port-wine colour is obtained. It disappears on heating. It is not a very sensitive test. It must be distinguished from a similar reaction after taking salicylates, but in this case the colour is not discharged by heat. Two tests with sodium nitroprusside are given both by aceto-acetic acid and acetone, but they are about twenty times as sensitive for the former as the latter. In Legal's test a small crystal of sodium nitroprusside or a few drops of a freshly prepared solution of it are dropped into the urine, and then a little caustic soda. A cherry-red colour is developed which soon fades ; an excess of acetic acid now added produces a carmine-red or deeper purple colour. In Rothera's test solid ammonium sulphate is added to the urine with a crystal of sodium nitroprusside and ammonia in excess. A purple colour gradually develops. This is much the most sensitive test there is for aceto-acetic acid.

These tests are excellent for indicating the presence of ketosis ; but they are not of much use in indicating its amount, in order to be able to determine whether a diabetic patient is on the verge of coma or not. One reason is that when coma approaches the excretory power of the kidneys begins to fail with fall of blood pressure, so that the amount of these substances in the urine is diminished, and inversely they accumulate in the blood. It is this accumulation that gives the measure of the danger. Three methods are available (*see* p. 452). The determination of the ratio of ammonia nitrogen to total nitrogen and the test of giving 5 grammes of sodium bicarbonate by the mouth have already been sufficiently described. The alveolar CO_2 method depends on the fact that the normal CO_2 values lie between 4.5 and 6.2 per cent., being rather lower in women than in men. In diabetes a value of 2 per cent. means that coma may supervene within twenty-four hours, if no improvement takes place. A patient may go on living for many days or even some weeks with the alveolar CO_2 between 3 and 4 per cent. In the worst event coma will not supervene before three or four days. It has already been stated that the lowering of the CO_2 which is caused by increased respiration is a mechanism compensating for the increase of fixed acid in the blood, and this prevents the hydrogen ion concentration of the blood rising too much.

Symptoms. The onset of diabetes is often insidious ; the patient only gradually notices that he drinks more fluids and passes more urine than normal ; or he may complain of debility and loss of flesh rather than of any alteration in his urine. In some cases the onset is acute, the patient being able to remember the exact day when he first noticed he was thirsty.

In the more severe type of case, which may come on acutely or develop from a milder type, the characteristic symptoms, in the absence of treatment, soon become unmistakable—namely, frequent and abundant micturition, great thirst, generally a very large appetite, physical weakness, and loss of flesh. The appetite is sometimes enormous, but in other cases it is but little affected, and often fails towards the end. The mouth and lips are dry, the tongue red, raw, and “beefy” ; and there is generally a sweet taste in the mouth. The digestion is, as a rule, good, and patients may have no difficulty in disposing of large quantities of food. The bowels are generally confined. The skin is harsh and dry. At the same time, nutrition is profoundly affected ; the patient rapidly loses flesh, and becomes excessively weak ; he is indisposed to make any mental effort, and is depressed and irritable. The teeth become loose from pyorrhœa alveolaris. There is often loss of virility in men, and in women the menses may cease.

The urine is increased to 5 or 10 litres in the day, the amount of sugar passed being over 500 grammes and the concentration up to 8 per cent. Owing to the presence of so much sugar, the specific gravity is raised to 1,040 or 1,045. The urine is generally pale yellow, or almost like water; it has a sweetish odour like hay and a sweet taste. The reaction is acid. It contains acetone, aceto-acetic and β -oxybutyric acids.

Mild cases of diabetes are sometimes described as "alimentary glycosuria"; but blood sugar tolerance curves show that this is a type of true diabetes, although the glycosuria may be found only after a heavy meal containing much starch. There is no thirst, and the amount of sugar passed in the day may be under 50 grammes. There may be no symptoms, but often the patients notice that the volume of urine is increased. They may suffer from various complications. This type occurs in elderly people particularly.

Complications. In the course of diabetes a number of complications are liable to occur. The irritation of the saccharine urine may excite in women a troublesome *pruritus* of the vulva, and in men *balanitis*. There may be a general *pruritus* of the skin. *Carbuncles* and *boils* are liable to occur in various parts of the body, and the former may be the cause of death. A form of *xanthoma* has also been seen in diabetes. There is sometimes *gangrene* of the toes or of an entire limb, but this is associated with atheromatous arteries. *Albuminuria* may be present, indicating coincident renal changes. The Achilles jerks and knee jerks are commonly absent in diabetes; this may be due either to *peripheral neuritis* or to degeneration in the fibres of the *posterior nerve roots* between the pia mater and grey matter, which leads to changes in the posterior columns of the cord (11). *Neuralgia* may be severe, especially sciatic, occipital and trigeminal. There may be cramps. *Edema* of the feet and legs may be seen in very wasted individuals (*cachectic edema*), and it can be readily produced by administering too large doses of sodium bicarbonate. *Phthisis*, *pneumonia* and other infectious diseases do not occur more commonly among diabetics than among the general population; but the outlook is worse, although it has improved with modern methods of treatment.

Vision is affected in diabetes in several ways. Rapid alterations in focussing power and amblyopia may be due to weakness of the ciliary muscle or to changes in the refractive index of the media presumably from the presence of sugar. Diabetic *cataract* is usually of the senile variety; but in young persons a posterior polar cataract due to diabetes may be found, though it is very rare. A retinitis similar to arteriosclerotic retinitis is common in elderly patients; possibly both the diabetes and the retinitis are secondary to arterial disease, and there is no direct connection between the two. Other changes are iritis, retrobulbar neuritis causing optic atrophy, hæmorrhages in the retina and vitreous, and *lipæmia retinalis* already mentioned in severe untreated cases.

Diabetic Coma. This name has been given to a group of symptoms due to the accumulation in the blood of aceto-acetic acid, which acts as a poison both on the circulatory and on the central nervous systems, and with a fatal result. Deficiency of CO_2 in the blood may also play a part in the causation of this symptom complex. The causes predisposing to coma are: (a) a diet rich in protein and fat; (b) excitement or emotional shock; (c) general anæsthesia: probably gas with oxygen is the least harmful, but it is very important that the patient should not get blue; (d) acute infections; (e) impaired function of the kidneys, so that aceto-acetic acid is imperfectly excreted; (f) constipation; (g) failure to continue the use of insulin in a young patient, who has put on fat by its help. The onset is often gradual, but may be indicated by loss of appetite, by a rapid fall in the quantity of urine and of sugar passed in the day, by the presence of albumin and casts in the urine, and by obstinate constipation. Sometimes there is severe abdominal pain. The patient then rather rapidly falls into a condition of collapse and coma. The pulse is quick and

feeble, the intraocular tension lowered, the surface cold, the features pinched, and the extremities livid. He lies with the eyes half open, taking no notice of his surroundings; and though he can be roused by a question, he answers, if at all, in a dazed manner, as if only half comprehending it. The breathing in these cases is peculiar; it is slow, deep, and sighing in character; the movements of the chest are very extensive; the respirations become rather more frequent towards the end. At the same time, examination of the chest reveals nothing abnormal. This form of breathing has been called *air hunger*. In many cases a sweetish, fragrant, or ethereal odour, likened to the smell of apples by some, may be noticed about the bed of the patient; it has been attributed to acetone. This condition may last from one to three days, when the pulse gets more and more feeble, though the heart may be beating forcibly, the patient more apathetic, and finally quite comatose; and death ends the scene. Occasionally there is a little muttering delirium. In some cases the symptoms are much more rapid; without any warning the patient becomes collapsed, with a quick, feeble pulse and livid extremities; air hunger develops, and he dies in coma after twenty-four or thirty-six hours.

Renal Glycosuria. *Benign Glycosuria (Diabetes Innocens).* These terms are applied to a condition where the patients pass sugar continuously for years, but remain in perfect health and have none of the symptoms of diabetes. The output of sugar is small, being usually not more than 30 grammes in the day. A dose of carbohydrate makes little difference to the output. In some cases it is difficult to get rid of the sugar by treatment, in others it disappears rapidly with starvation. The blood sugar tolerance curve is normal (see p. 464). The blood sugar on an empty stomach is normal, and yet sugar is passed, showing that the threshold of the kidney is low. The ætiology of the condition is unknown, but occasionally it is congenital. No treatment is required. Glycosuria associated with a low renal threshold occurs experimentally when an animal is poisoned by phloridzin.

Diagnosis. The presence of sugar in the urine as determined by one of the reduction tests, when there is also a present or past history of either thirst, polyuria or muscular weakness, makes the diagnosis of diabetes mellitus certain. If the urine is not tested, the presence of the disease may be overlooked, and the patient may be treated for a vague weakness and "debility"; or the possibility of diabetes underlying one of its complications, such as carbuncles, pruritus, or coma, may be forgotten. It must be borne in mind that coma may occur as a result of diabetes in persons not known to be diabetic; and that in diabetics abdominal pain, severe enough to suggest that a laparotomy is needed, may be the first symptom of the onset of coma. The chief difficulty is when a patient's urine gives a slight reduction on several occasions and there are no symptoms. The fallacies connected with the clinical tests have already been considered; but even if the presence of dextrose is proved by the fermentation and phenylhydrazine tests, it is still necessary to find out if the patient is suffering from true diabetes mellitus. If the blood sugar is above 0.16 the diagnosis will be very probable, but if lower than this it will be best to carry out a sugar tolerance test with analyses of the blood after a dose of dextrose, and this will also assist the prognosis.

Prognosis. Diabetes mellitus is a very serious disease, tending to run a more rapid and unfavourable course in young than in elderly subjects. At the same time the prognosis has improved with the introduction of insulin and careful dietetic treatment. In some cases the sugar tolerance increases as the result of treatment; but a cure must be very rare—in the sense that the patient is able to live without insulin on an unrestricted diet and yet keep a normal blood sugar. Without treatment the prognosis is uniformly unfavourable in young subjects, as the disease tends to progress. It may progress in spite of treatment, especially if the patient becomes infected. The prognosis is the more unfavour-

able the later in the disease that treatment is instituted. In elderly subjects with so-called "alimentary glycosuria," a fatal result need not occur in the absence of treatment; but there is always the possibility of complications such as carbuncle, cataract and retinitis, so that adequate treatment should always be instituted to prevent these occurring.

Prevention. Since early treatment is so important, the periodic examination of the urine has been recommended. This should certainly be carried out in the case of the healthy members when diabetes runs in a family. The best way of avoiding diabetes is to live a healthy life with plenty of regular exercise and to avoid obesity and focal sepsis.

Treatment. The first treatment of diabetes on rational lines was carried out by Rollo, who prescribed a diet of animal food containing no starch and sugar. This plan was very generally adopted up to 1915, enormous amounts of protein and fat being allowed. It was comparatively rare for the urine of a diabetic to become sugar-free on such a diet. Experiments carried out on depancreatized dogs by F. M. Allen and clinical observations at different times by Von Noorden, Guelpa and Graham showed the importance of undernutrition in treatment. The plan usually adopted consisted in first of all making the urine sugar-free by fasting and then in giving food in gradually increasing amounts, in severely restricting the carbohydrate intake, and in permanently underfeeding the patient, so as to keep him thin. In an underfed person the basal metabolism is low, so that there is less call on the island tissue, and this is of great advantage where the islands are deficient as in diabetes, because they steadily deteriorate if they are overworked. A high protein diet causes a high metabolism; this has been called the *specific dynamic action* of protein. The treatment of diabetes has been revolutionised by the discovery of insulin; but although fasting is now no longer necessary, an arranged diet is still usually necessary, particularly in the more severe cases.

At the beginning of treatment possible focal sepsis which may be due to dental apical infection, septic tonsils, gall bladder, or appendix should be eradicated. The aim of treatment is to administer insulin in such quantities and at such times that the blood sugar remains within normal limits during the twenty-four hours.

The principles of treatment can be deduced from Dr. W. W. Payne's determinations of the blood sugar of a patient shown in Fig. 59. Curve B is on the average higher than curve A, because carbohydrate was substituted for some of the protein. Otherwise the diet was the same in A and B. The effect of giving insulin twice a day at twelve hours' intervals before breakfast and supper, is, broadly speaking, to produce a double curve, a rise immediately after the meal followed by a fall. In this case, with rather a smaller dose of insulin, the morning rise was much higher than the evening rise; in curve A the rise certainly began before breakfast, and may be explained by the increased metabolic activity which suddenly occurs on waking. In other cases, with equal doses of insulin, the evening rise may be the higher, and when three doses of insulin are given at 6 a.m., 12 noon, and 9 p.m., *i.e.* after supper, a triple curve is obtained which may be just as high at night as in the day, presumably because protein metabolism takes place more slowly than carbohydrate metabolism, and so is delayed till night-time (12).

When treatment is first begun, injections of 4 or 5 units are given half an hour before breakfast and supper. The dose is increased by 4 or 5 units every two or three days. The sugar in the urine becomes less and eventually disappears. At this stage the renal threshold may be determined by estimating the sugar in the blood after emptying the bladder, and testing for sugar the urine which is secreted during the next 15 minutes. If the threshold is normal (0.16–0.18 per cent.) the absence of sugar in the urine passed at frequent intervals in the twenty-four hours will indicate that the blood sugar has never been too high;

The patient sits on the floor with his back pressed firmly against the wall and his knees bent. The body length is measured from the floor to the top of the head in inches and compared with the body weight without clothes in pounds. If the patient is too fat or too thin owing to disease, then his predicted metabolism would be best obtained by using in Plate 37 the average weight corresponding to his body length and not his actual weight. Table 3 is of general use to indicate at any time whether a patient is too fat or too thin.

Diabetic patients are nowadays treated more generously as regards carbohydrate than formerly, and provided the total calorie value of the diet is not excessive the insulin requirement is not higher than with low carbohydrate diets. In fact, the high carbohydrate low fat diet with a ratio of 6 to 1 often succeeds in bringing down the blood sugar to normal in an obese patient without insulin being used at all; but if such a diet is used for any length of time vitamins A and D must be supplied extra. In order to facilitate the prescribing of diets the author has calculated a number of diet formulas, some of which are given in the table. Each formula contains a definite number of carbohydrate rations of 20 grams each, of fat rations of 10 grams, and of protein in grams. Additional formulas may be calculated by adding and subtracting the top line which corresponds to 200 calories. In making out these ratios no account is taken of protein as a source of carbohydrate or fat; such calculations are too hypothetical, and with higher carbohydrate diets the glycerol of fat is unimportant as a source of carbohydrate. A carbohydrate to fat ratio of 2 to 1 will be found most generally useful though children may prefer 4 to 1, while a higher carbohydrate diet may be of special value in arteriosclerosis, angina pectoris, sepsis and phthisis. The old-fashioned diet corresponds to 1 to 1. The carbohydrate and fat rations are obtained from Lists A, B and C, which give the amount of each foodstuff corresponding to a whole and a half carbohydrate or fat ration, while in List D there are foods containing carbohydrate, fat and protein including a few recipes for ordinary household use. A diabetic may eat any food that the normal subject customarily takes provided its composition is known, and this scheme of diets enables him to take part in the ordinary meals of the family. A much more detailed list containing 200 recipes, is being published elsewhere (54). Dishes containing sugar should usually only be taken shortly after insulin, *i.e.* at breakfast and supper; but many physicians forbid it altogether. An allowance is made for vegetables, but apart from potatoes, butter beans and peas, weighing is not necessary. Clear broth can be taken freely. There is not the same object in giving alcohol as in the old days and it is better avoided. Beers contain from 4 to 8 per cent. carbohydrate. Saccharine may be used as a sweetening agent. These diet tables take account mainly of carbohydrate and fat; a variation in the protein is not of much consequence as the calorie value is low compared with fat. It is much more convenient to weigh the food in grams and so avoid the awkwardness of fractions which come in when ounces are used; both measures are given in the tables. Most of the carbohydrate should be given at breakfast and supper, shortly after the insulin; but some may be given at the midday meal and even at tea-time in milder cases. With large doses of carbohydrate it is often advisable to give the insulin three-quarters of an hour or even one hour or more before the meal so that it will produce its maximum effect from one to two hours after the meal when the blood sugar rise is at its maximum; but if the insulin is advanced too much there will be a reaction before or during the meal.

Choice of Case for Insulin Treatment. Insulin treatment must not be used for renal glycosuria. The glycosuria of pregnancy is frequently of this nature; but where pregnancy is complicated by true diabetes the woman should be given the choice as to whether the pregnancy should be terminated or not, and if not, insulin treatment should be instituted. The success of insulin in removing symptoms in practically all patients with glycosuria and hyperglycæmia indicates

LIST A.—20 GRM. CARBOHYDRATE RATIONS (C.R.).

These amounts also
contain protein.

20 grm. carbohydrate are contained in :	Grm.	or Oz.	Grm.

+ Foods thus marked contain more than 10–11 gm. soluble carbohydrate in the stated portion and should only be ordered by a physician.

RECIPES.

(1) *Fruit Cake*. ½ lb. flour, ½ lb. sultanas, ½ lb. sugar, ¼ lb. butter, 2 eggs, 2½ oz. milk, 10 gm. Royal baking powder (a teaspoonful). In oven 1 hour.

(2) *Sponge Cake*. 6 oz. flour, ¼ lb. sugar, 2 oz. butter, 2½ oz. milk, 2 eggs, 5 gm. baking powder (a level teaspoonful). In oven 35 min.

(3) *Cheese Straws*. 70 gm. (2½ oz.) cheese (Parmesan), 113 gm. (4 oz.) flour, 62 gm. (2½ oz.) butter, yolk of 1 egg, ½ oz. water, salt, cayenne pepper. Sieve flour, rub in butter, add grated cheese and seasonings, bind with slightly beaten yolk of egg and water to form a stiff dough, knead lightly, roll out thinly and cut. Time in oven 15 min.

(4) *Macaroni Cheese*. 54 gm. (2 oz.) macaroni [or 53 gm. (1½ oz.) spaghetti], ingredients of Sauce No. 11, 62 gm. (2½ oz.) Cheddar cheese. Soak macaroni in water for an hour, add salt and boil until tender, strain. Prepare hot sauce and add macaroni and most of the cheese, season well with mustard and salt, transfer to pudding dish, sprinkle remainder of cheese on top of pudding and brown in oven. Time, 45 min.

(5) *Mashed Potatoes*. Boil 200 gm. (7 oz.) peeled old potatoes until tender, pour off water, and steam slightly to finish cooking. Cooked like this there is no alteration of weight. Mash with 1 oz. milk, 12 gm. (½ oz.) butter, add pepper.

(6) *Batter Pudding*. (a) 70 gm. (2½ oz.) flour, 1 egg, 6 oz. milk; 12 gm. (½ oz.) butter for basin; mix, beat and cover, allow to stand, beat occasionally. Heat steaming bowl with butter thoroughly melted. Time, 1 hour. (b) It may be baked 40 min.

(7) *Bread and Butter Pudding*. 57 gm. (2 oz.) white bread, 6 gm. (½ oz.) butter, 1 egg, 10 oz. milk, 21 gm. (¾ oz.) sultanas. Time 2 hours.

(8) *Savoury Pudding*. 57 gm. (2 oz.) white breadcrumbs, 16 gm. (½ oz.) butter, 2 eggs, 7 oz. milk, 1 medium size onion, mixed herbs or chopped parsley, pepper and salt. Shred onion and boil in salted water until tender, beat eggs, mix ingredients together and season well with herbs, pepper and salt, butter dish and bake for 40 to 50 min.

(9) *Suet Pudding*. 49 gm. (1½ oz.) flour, 22 gm. (¾ oz.) shredded suet (Atora), 1½ oz. milk, 4 gm. Royal baking powder, salt. Sieve flour, baking powder and salt. Add suet mix in milk with knife. Use knife for arranging mixture on fruit as a "Cap" in No. 6. (a) It may be covered with greaseproof paper and steamed 80 minutes, or (b) baked in oven 30 minutes. (c) If dumplings in a Silverside stew are required, use 67 gm. (2½ oz.) flour in mixture and 10 gm. (½ oz.) flour for covering the dumplings.

(10) *Yorkshire Pudding*. Same mixture as No. 15, but use dripping for baking dish instead of butter. In oven 25 min.

(11) *White Sauce, Pouring*. 14 gm. (½ oz.) flour, 4 gm. (¼ oz.) butter, 6½ oz. milk, salt and pepper. Melt butter and mix with flour, add milk by degrees, stir constantly and boil up after each addition. Boil for five minutes. Add seasonings.

(12) *Bread Stuffing or Force Meat*. 29 gm. (1 oz.) white breadcrumbs, 12 gm. (½ oz.) butter, margarine, or dripping, ¼ oz. milk, mixed herbs, pepper and salt. Rub butter into breadcrumbs, add seasoning, mix and moisten with milk. To be used for beef or veal olives or liver, in larger quantities for stuffing fowl, game, galantines or fish, or made up as balls to be stewed for 10 min. in boiling stock; 6 gm. (½ oz.) flour to be used in the cooking.

				10½	10½	89.0	

that in all such cases the pancreas is primarily at fault, and it is reasonable to supply the deficiency by administering insulin, and this should certainly be done when complications are present such as gangrene, cataract, phthisis, angina pectoris, etc. In very mild *elderly* cases a diet with a C to F ratio of 1 to 1 of rather low calories will often be sufficient by itself to bring down the blood sugar to normal, though ketosis should be avoided. It is just in these cases that the high carbohydrate low fat diet may also be used with success, without insulin. In *young* subjects, however mild the case, insulin treatment should be instituted at once both to prevent the disease becoming worse and by resting the islands to produce some curative effect. Dextrose, say 2 ounces, should be given half an hour before a general anæsthetic, and 20 units of insulin half an hour before this.

After-Treatment. Patients must be taught to administer insulin to themselves, and should know how to test the urine for sugar. In elderly patients insulin may be discontinued at any time and no harm will result. Its administration may also become unnecessary. In the young the dose of insulin should be the maximum that the patient can tolerate without producing symptoms. With a normal threshold the urine should always be sugar free, and the Rothera's test for ketosis always negative. A positive Rothera's test often occurs when too little insulin is being used, so that the blood sugar remains above normal (14), but it is also due to there being too little carbohydrate or too much fat in the diet, and some modification should be made if this is the case. Patients should take less insulin if they are to take unaccustomed muscular exercise, since the latter tends to lower the blood sugar. A patient treated along the lines just laid down may find after a time that the dose of insulin to which he is accustomed is becoming too large, since he is experiencing hypoglycæmic reactions. This means that he is improving, and the dose must be diminished. If a cure with insulin is possible, it will certainly require some years before it is complete.

Infection. When the patient gets any acute infection such as tonsillitis, influenza, measles, pneumonia, gastro-enteritis, etc., the call by the body for insulin is increased.

(a) If the usual food is being taken, the ordinary dose of insulin is given. The urine should be tested every two or three hours, and if sugar appears a fresh dose of insulin should be administered before the midday meal, or at midnight (an extra feed being given). A gradual increase in the dose may also be necessary; but the insulin must, of course, be diminished as soon as the temperature falls and the urine remains sugar free.

(b) Suppose that no food is being taken (*e.g.* if there is vomiting). (1) If the urine contains sugar, the full dose of insulin should be given at the usual time, and the urine should be tested every two or three hours with fresh additions of insulin as has already been described. (2) If the urine does not contain sugar, half the usual dose of insulin should be given, and the urine tested every two or three hours, and fresh doses of insulin given if necessary. In both cases it would be better

to give glucose in 10 per cent. solution (a gramme per unit) half an hour after the insulin.

Diabetic Coma. At the beginning of diabetic coma a large dose of insulin, *e.g.* 60 units, should be given in part subcutaneously and in part intravenously with 60 grams of sugar by mouth in a pint of water, and the subcutaneous injection and sugar should be repeated every four hours, until the urine becomes free of ketone bodies; insulin and sugar are then continued in smaller doses at longer intervals. It is important to test every specimen of urine for sugar as it is passed, and to catheterize the patient in order to get a specimen, if there has been no urine to test for three or four hours. The reason for these precautions is that with the vigorous treatment necessary for diabetic coma, it is possible for the patient to pass into hypoglycæmic coma, without any intermediate return of consciousness, though this is unlikely if sugar is given as described.

An additional very important method of treatment is to give large amounts of fluid, containing the sugar and perhaps sodium bicarbonate. This will have the effect of keeping up the flow of urine and so will help to get rid of the poisonous aceto-acetic acid, which is probably the cause of diabetic coma. A stomach tube, Einhorn's tube, or a long nasal tube and funnel are essential for administering the fluid to an unconscious patient. The patient is made to lie on the right side, so that the fluid will gravitate at once towards the duodenum. A pint of warm sterile, isotonic solution is given every hour until a free flow of urine is established. On no account should this treatment be stopped if the patient vomits, but the actual duration of the administration should be prolonged so as to prevent distension of the stomach. Care must be taken by frequent examination to see that œdema of the lungs does not develop. From twenty-four to forty-eight hours of such treatment will be required before the patient becomes fully conscious after being in deep coma. When death occurs in spite of vigorous treatment, uræmia may be the cause, since in several cases the blood urea has been found to be high (12, 13). The patient must be kept flat to avoid heart failure.

Hypoglycæmia. The symptoms of hypoglycæmia have already been given. There is no danger of severe hypoglycæmia in the early stages of treatment, if the latter is carried out correctly. Later on, it may result from severe muscular exertion, especially if large doses of insulin are being taken in order that a high carbohydrate diet may be metabolised. Patients should carry some lumps of sugar with them to eat in case of emergency.

The symptoms of *hypoglycæmic coma* are to a certain extent the converse of diabetic coma. There is profuse sweating, the pulse is full and bounding, the veins stand out prominently. There may be some œdema of the lungs with cyanosis and fluid expectoration. The patient is convulsed, and there are no ketones in the urine. One patient complained of not being able to breathe. Hemiplegia has been reported. In a case of *hypoglycæmic coma* a subcutaneous injection of 15 to 20 minims of adrenalin (1 in 1,000), or failing this the same dose of pituitrin, may be given. This treatment will be of value if the liver contains a good store of glycogen. Plenty of sugar—4 to 8 ounces of cane sugar or dextrose—is given by mouth or by stomach tube. If the patient does not recover consciousness rapidly, an intravenous injection of a 5 or 6 per cent. solution of dextrose is given.

Spontaneous Hyperinsulinism. So far the hypoglycæmia of insulin administration has alone been dealt with. Spontaneous hyperinsulinism results from a tumour or hyperplasia of the cells of the islands of Langerhans. A number of cases of typical hypoglycæmic symptoms have now been described (*see p. 471*) with faintness or coma coming on if the patient went too long without food, and these have been relieved by giving sugar. Operation has sometimes disclosed the causal condition and the lesion has been successfully removed. Deep X-ray might be considered as an alternative method of treatment. In other cases a normal pancreas has been found and the problem as to the cause of

the symptoms has remained unsolved. Occasionally the liver may be responsible, though hypoglycæmia from liver disease usually means a very extensive involvement, and other signs of hepatic deficiency would be expected. There is the following possibility, though proof has so far been lacking.

Anterior Pituitary Deficiency. One of the many functions of the anterior lobe of the pituitary is to act as an antagonist to insulin. The diabetes of acromegaly is well known. Experimentally, it has been found that if in a depancreatized dog the pituitary is also removed, the animal loses his diabetes and the blood sugar may change from above to below normal. If the pituitary is removed alone, the normal antagonist to insulin is missing and hypoglycæmia readily occurs after fasting or exercise, and this can be remedied by giving sugar. In such a case preparations of anterior pituitary might be tried. Hypoglycæmia has been observed in the so-called pituitary cachexia of Simmonds's disease (*q.v.*).

Other cases of hypoglycæmia are excessive muscular exercise as in marathon runners, and exhaustion of glycogen stores by thyroid feeding. See appendix on p. 504.

THE THYROID GLAND

The normal thyroid gland contains cells which secrete colloid from which an iodine-containing crystalline substance, called *thyroxin*, has been isolated.

The human body normally contains about 8 to 14 milligrams of this substance ; it is constantly being slowly formed, probably through the stage of di-iodo-tyrosine (48), and destroyed. The colloid is stored in the vesicles of the gland, having been secreted by the cells lining the vesicles, and after storage these cells become flattened and quiescent. Active secreting cells are cubical or columnar ; they are arranged in the form of acini and are richly supplied with dilated capillaries. The thyroxin secreted may either become discharged into these capillaries, and so into the general circulation, or it may be stored as colloid in the acini producing a vesicle ; at this stage the secreting cells become quiescent. Activity of the thyroid is indicated by increased secretion and by discharge of the colloid, probably through clefts between the lining cells (15). Thyroxin acts by stimulating the sympathetic nervous system, possibly by stimulating the adrenal medulla ; an increase of adrenin has been found in the blood. The thyroid-adrenal apparatus also stimulates the liver to form glycogen as already explained and to mobilise it as glucose in the blood stream ; the respiratory exchange is increased and the body temperature tends to be raised. Exposure to external cold stimulates this apparatus to increased functional activity, while heat inhibits it, and it is possible that fever is due to the action of bacterial toxins on this apparatus. It has been suggested that whereas the action of the adrenal is quick and short, the action of thyroxin is slow and sustained. The action of the thyroid on calcium metabolism is described under exophthalmic goitre.

The term goitre means an enlarged thyroid gland. It occurs in the following forms : (1) Hypertrophy, with the vesicles and secreting acini scattered diffusely through the gland. This is the goitre of puberty, pregnancy and the menopause, and it may follow oöphorectomy or ovarian disease ; (2) Colloid goitre ; (3) encapsuled adenoma, which may be solid or cystic (these three enlargements constitute forms of endemic or sporadic goitre) ; (4) primary exophthalmic goitre ; (5) secondary Graves' disease or toxic adenoma ; (6) malignant disease.

ENDEMIC OR SPORADIC GOITRE

Ætiology. Goitre is frequent in certain localities. In England it occurs in Derbyshire and in the West and South-west of England and Wales (16) ; it is commoner in the country than in the town. On the Continent it is frequent in the mountainous regions of Savoy, Switzerland, Northern Italy, the Tyrol, and

Styria. It is not, however, confined to the hills, but spreads down into the villages on the plains beneath. Endemic goitre may result from lack of iodine and tends to occur among people who live far away from the sea. It also results from an increased requirement for iodine, which is unsatisfied. Various factors may contribute to this increased requirement: contamination of drinking water with some organic material in the soil, possibly faecal; infection, since acute goitre sometimes occurs in epidemics (17); unidentified substances (possibly cyanins, which inhibit tissue oxidation) in cabbage and certain other vegetable foods; excessive ingestion of fat; puberty and pregnancy; lack of vitamins A and C may cause goitre in experimental animals in spite of there being plenty of iodine present (47). Goitre is commonest in females and in young people. Sporadic goitres occurring in non-goitrous districts are to be explained along these same lines. Endemic goitre is often found to be associated with *myxœdema* and *cretinism*.

Pathology. A deficiency of iodine stimulates activity on the part of the gland as already described, with proliferation of secreting cells, increase of fibrous stroma and blood supply, and absence of colloid. At any stage in the process there may be involution with complete recovery. On the other hand, this active stage may be followed after some years by degeneration of two kinds: (a) atrophy of the cells and their replacement by fibroblasts, leading on to fibrosis and cyst formation, or (b) great enlargement with increase in the colloid of the gland—"colloid goitre," which represents a resting stage of the gland with accumulation of colloid and iodine after the period of previous activity, due to want of iodine. Adenomas of the thyroid probably arise from cell rests which grow under the same stimulus that produces colloid goitre. The differentiation of adenomas from colloid goitres is not absolutely clear cut, and intermediate types are common. Adenomas may pass through the same stages of involution, atrophy, cyst formation, or colloid formation, as affect the whole gland. As a rule adenomas are multiple and develop about the age of puberty. The size of a goitre varies from a moderate prominence of the neck on either side to a mass as large as the fist or a foetal head, which hangs down in front of the upper part of the sternum, such as those which have been so common in Switzerland and Savoy. In the lymphadenoid goitre, there is epithelial keratinisation with aggregation of lymphocytes in the gland and ultimate fibrosis; vitamin A deficiency is a cause.

Symptoms. Enlargement of the neck and a feeling of fulness are often the only symptoms. If the goitre is very large, there may be dysphagia from pressure on the œsophagus, or dyspnœa from compression of the trachea, or of the recurrent laryngeal nerves. If there are any symptoms other than the local effects of the enlarged gland, they are indicative of diminution of the thyroid function, or hypothyroidism (see *Myxœdema*). The basal metabolism is normal or slightly reduced in colloid goitre.

Carcinoma occurs generally after middle age, and forms a hard, rapidly growing tumour, which infiltrates and presses upon surrounding parts. The functions of the gland are generally carried on; and if in such a case there are secondary growths in internal organs, the total removal of the thyroid does not cause myxœdema.

Diagnosis The thyroid nature of any enlargement is proved by its movement up and down with the larynx during the act of swallowing.

Treatment. Prophylaxis in areas of endemic goitre consists in administering 0.1 gramme of sodium or potassium iodide once a day for ten days in the spring and autumn. In the canton of Appenzell, in Switzerland, 0.25 to 0.5 gramme of potassium iodide has been added to each kilogram of salt, so that all the inhabitants cannot fail to get some. Abnormalities in the diet, as described in the ætiology, must be corrected. Congenital goitre can be prevented by treating the mother during pregnancy. In the treatment of the earliest stage of goitre, when

adenomas are not present iodine may be given internally as tincture in doses of 2 or 3 minims thrice daily. The administration of iodine has caused adenomatous goitres to overact, and hyperthyroidism may continue for years without further administration of iodine. Iodine does not intensify the hyperthyroidism of true exophthalmic goitre. Iodine treatment is not so successful in a developed colloid goitre, and thyroid extract may be tried. Surgical measures may be necessary in very hard or very large goitres and in malignant disease, if recognised sufficiently early; they are the enucleation of an encapsuled tumour and the removal of the greater part of the gland. The Röntgen rays may also be employed.

EXOPHTHALMIC GOITRE

(*Graves' Disease, Basedow's Disease*)

This disease, occurring more frequently in women than men in the proportion of 3 to 1 (18), was first described by the Dublin physician Graves in 1835, and by a German physician, Basedow, in 1840. The prominent symptoms are: protrusion of the eyeballs, enlargement of the thyroid gland, frequent action of the heart, and tremor.

Ætiology. Broadly speaking cases fall into two groups; but there is no hard and fast line between the two groups and the distinction has been considered rather artificial.

(1) *Primary Exophthalmic Goitre.* The onset is sudden and there are frequent remissions and exacerbations. There are corresponding alterations in the respiratory exchange or basal metabolic rate (*see p. 459*). The latter is high when the disease is severe, and *vice versa*. It occurs usually in young persons. Sometimes there has been a neurotic tendency, as shown in hysteria or epilepsy, or mental disease in the family. In a few cases it has followed rapidly upon some emotional or mental excitement, or even direct injury to the head. Hyperthyroidism was frequently noticed among soldiers during the war, and was due to the intense mental strain. A hereditary connection has sometimes been observed: it has been observed in mother and son or daughter; more often it attacks brothers and sisters in the same family. The fact that the incidence of exophthalmic goitre was diminished in Germany during the war suggests that abundant feeding may help in its causation (19). The distribution of exophthalmic goitre in England and Wales is rather similar to that of endemic goitre; the incidence is greater in rural districts than in towns (16).

(2) *Secondary Graves' Disease.* There is often a history of previous swelling of the thyroid, indicating that the gland has been for some time the site of chronic changes. Symptoms of over-activity often begin to develop about the age of thirty-five or forty years, and may result from the administration of iodine to a case of adenoma. The disease pursues a steady course over years with symptoms that gradually become more severe. There are no remissions. There is a slow, steady increase in the respiratory exchange. Exophthalmos is often not very marked. There is a special liability to cardiac irregularities, such as auricular fibrillation, and advice may first be sought on account of cardiac failure. When there is evidence of adenoma of the thyroid these cases are often called *toxic adenoma*.

Pathology. That the disease is due to hypertrophy of the thyroid producing an excess of thyroxin is shown by the resemblance of the symptoms to those which follow large doses of thyroid extract, by their contrast with those of myxœdema, and by the improvement which has occurred after partial excision of the hypertrophied gland. Discussion has, however, taken place as to whether the disease is merely due to an over-production of normal thyroxin or whether the thyroxin is altered in some way, for instance, by containing less iodine in the molecule than normal—whether there is a true hyperthyroidism or a thyrotoxicosis. The arguments in favour of the latter view are that the symp-

toms cannot be exactly reproduced by giving excess of thyroid to animals, *i.e.* there is no exophthalmos. Further, there are some cases in whom some symptoms of hyperthyroidism and myxœdema appear to co-exist; but this does not necessarily mean that the two diseases co-exist, because the hyperthyroidism symptoms may be a relic of a previous over-activity, which has now died down. On the whole, there is not sufficient evidence for the second view. It is probable that in some cases the activity of the thyroid may be due to stimulation by an excess of the thyro-tropic hormone from the anterior pituitary (*q.v.*).

The thyroid intoxication leads to stimulation of the sympathetic, increased mobilisation of glycogen by the liver and increased respiratory exchange. Patients are very tolerant to insulin, which antagonises thyroxin by inhibiting the mobilisation of glycogen. In fact, as far as their effect on the liver is concerned, diabetes mellitus and exophthalmic goitre resemble one another. But their effect on the muscles is very different, since in exophthalmic goitre the sugar is burnt there, but in diabetes this is largely prevented (15). The sympathetic stimulation may account for the exophthalmos, von Graefe's sign, tachycardia, and sweating. In Cannon's well-known experiment the phrenic nerve of the cat was sutured to the cervical sympathetic on the same side. The excitation of the sympathetic thus produced caused exophthalmos on the same side. The exophthalmos has been regarded as due to the stimulation of Müller's muscle, which lies in the membrane lining the orbit over the spheno-maxillary fissure; but in man the muscle is rudimentary, consisting of a few scattered fibres. Another possibility is that the eyeballs are pushed forward by œdema fluid, since œdema of the recti has been found, and then there follows a secondary deposit of fat.

The emaciation is due to the high respiratory exchange, combined with alimentary disturbances which hinder absorption. As the fat depôts become exhausted protein is drawn upon, so that there is also an abnormally high protein breakdown. In spite of the increased combustion, the body temperature is not raised, except occasionally, because, owing to profuse sweating, the loss of heat from the body is increased. There is a pronounced excretion of calcium not only in the urine but in the fæces too; in fact, depletion of calcium in a healthy subject is more readily brought about by thyroid extract than it is by parathormone or acids. In contrast to hyperparathyroidism (*q.v.*) there is no rise of blood calcium, in fact, this tends to be low (and yet thyroid extract *raises* the blood calcium in parathyroid tetany!); on X-ray examination the bones may show deficiency of calcium (21).

Morbid Anatomy. The vesicular and parenchymatous cells proliferate. The contents of the vesicles lose their colloid nature and become mucous and granular. In later stages the gland may become fibrous or cystic. In primary exophthalmic goitre these changes are diffused throughout the gland; in secondary Graves' disease some parts of the gland show activity; other parts show colloid storage, fibrosis and cyst formation; there may or may not be definite adenomatous changes present.

The thymus gland is often persistent and enlarged. A thyro-toxic myocarditis with necrosis and hyaline changes of muscle fibres occurs in long-standing cases (20).

Symptoms. The symptoms may come on suddenly, but generally they come on rather gradually, and, as a rule, the cardiac symptoms appear first, the protrusion of the eyeballs and the thyroid swelling not till some months later. Occasionally they may appear in a different order, or one or other of the three chief symptoms may be absent; but the circulatory trouble is the most constant. In the fully developed disease, the *heart* beats quickly and forcibly; the impulse is felt over an abnormally large area. The carotids and large arteries pulsate with great force, and the patient feels the violence both of the cardiac beat and the arterial throbbings. The pulse may reach 140. The electrocardiogram is often

normal ; but auricular fibrillation or a prolonged P.-R. interval may be present, and the T. and P. waves may approximate in size to one another (20). Very occasionally heart block is observed, especially if digitalis has been given in large doses. The patient suffers from shortness of breath on exertion in proportion to the cardiac disturbance. In course of time the heart may become hypertrophied and later dilated. Variations in pulse rate are usually followed closely by corresponding variations in basal metabolism ; but sometimes the pulse may still remain high, from damage to the heart, after the activity of the disease has died down, so that the basal metabolism gives a more certain picture of the activity of the gland.

The enlargement of the *thyroid body* is symmetrical, usually moderate in dimensions, and rarely equal to that of the larger endemic goitres. If the hand be placed over it, a thrill can be felt which is due to the movement of blood in its dilated vessels, and a systolic murmur can be heard with the stethoscope.

The *prominence of the eyeballs* (exophthalmos, proptosis) with widening of the palpebral fissure is the most striking characteristic of the disease, and gives to the patient an unpleasant, terrified, staring appearance. It affects both eyes, and may reach such a degree that the sclerotic is seen both above and below the cornea, and the eyelids are unable to meet. Even when the eyelids can be voluntarily closed, they may lie apart during sleep ; and if the exophthalmos is extreme, there may be irritation and ulceration of the cornea as a result of exposure. There is infrequent blinking (Stellwag's sign). In association with the exophthalmos there is a want of uniformity in the movements of the eyeball and the upper lid, so that, when the patient lowers the eyeball to look down, the upper eyelid is not depressed to a corresponding extent (von Graefe's sign). This is not present in every case, although it has sometimes been noticed even before the protrusion. On the other hand, when present it is of importance, as it does not occur in other kinds of exophthalmos. Weakness of the convergent muscles may be also present (Möbius' sign), and in some cases diplopia or definite paralysis of some or all of the ocular muscles. The pupil and accommodation are unaffected, and the ophthalmoscope reveals little beyond overfull and tortuous retinal veins.

A fourth very constant symptom is a more or less continuous fine *tremor* of the limbs, and even of the whole body. Muscular weakness and pain are also very characteristic. The patient has difficulty in extending the knees, so that going upstairs can only be carried out by pressing on the bannisters with the arms ; but the arms and trunk muscles may also be affected. There may be widespread paresis one evening and complete recovery the next morning after a night in bed. Is this associated with depletion of the body of calcium ?

The sufferer may be irritable, restless, or hysterical, but not anæmic. In some cases melancholia, hallucinations and even mania have occurred ; and tetany is an occasional event. The nervousness and cardiac action are increased by attention or by any excitement. The patient is generally thin, and may waste a good deal. A moderate degree of fever is occasionally present ; and some patients show various pigmentary changes of the skin, such as moderate bronzing, chloasma or leucoderma. A subjective feeling of heat, flushing of the head and neck, sweating and intermittent albuminuria have been noticed in different cases. Patients are very subject to attacks of diarrhoea, sometimes with vomiting. Glycosuria sometimes occurs, owing to hyperglycæmia ; that is, the patient cannot take the normal amount of sugar without its appearing in the urine. True diabetes mellitus sometimes follows, and patients with Graves' disease have sometimes died of diabetic coma. The fasting blood sugar is, however, usually normal ; but the sugar tolerance curve is rather delayed. The symptoms are liable to aggravation from time to time.

Diagnosis. There is difficulty in diagnosis in the early stages, before exophthalmos or swelling of the thyroid is noticeable. The disease must be

distinguished from tuberculosis. A persistent tachycardia with a normal electrocardiogram is suggestive, especially if there is sweating as well. However, auricular fibrillation is common in secondary Graves' disease. The respiratory exchange should be measured (*see* p. 459), which also indicates the severity of the disease. A blood calcium of 9 mg. or under and a threshold excitability for muscular contraction under 2 milliamperes are also suggestive.

Prognosis. Campbell has followed up the histories of 127 cases treated medically at Guy's Hospital between 1908 and 1917. The results agreed very closely with a similar investigation carried out previously by Hale White. At the end of the period 8 per cent. were absolutely well; 30 per cent. were almost well and able to do a full day's work, but one or two signs persisted slightly; 34 per cent. were much improved, being able to do light work; 13 per cent. were not improved or worse; 15 per cent. were dead from the disease. There is a very great improvement in the prognosis if treatment by means of operation or deep X-rays is carried out. In 60 per cent. of cases the patient will be able to do full work without difficulty (49, 50).

Treatment. A simple satisfying diet with plenty of carbohydrate should be employed. Alcohol and tobacco are likely to be prejudicial. Rest in bed for some weeks certainly has a beneficial effect on patients. In a series of fifty-one patients in which this was the only treatment, three-quarters had a basal metabolism under 18 per cent. within six months (4). When the patients get up very mild exercise should be allowed; but plenty of rest should be taken. Exophthalmic goitre cases are tolerant to insulin, and some benefit may be produced by giving 15 or 20 units twice a day on a normal diet, possibly combined with parathyroid $\frac{1}{10}$ grain three times a day by mouth (23). The application of ice to the thyroid is soothing.

There are two chief methods of reducing the activity of the thyroid, viz., (1) Deep X-rays; (2) removal of the gland by operation preceded sometimes by ligation of one or two thyroid arteries. X-rays are usually employed at the beginning of the disease and operation may be considered later if no improvement results. Prolonged X-ray treatment makes subsequent operative treatment more difficult. In true exophthalmic goitre great temporary benefit may be obtained by giving Lugol's solution (5 per cent. iodine in 7.5 per cent. potassium iodide solution), 15 drops once a day. The metabolism falls to normal in a week or two. A similar result may be obtained with iodine in 10 per cent. alcoholic solution. The dose is 15 minims a day, and this is reduced to 3 or 4 minims after a week or two (22). This treatment may be of great value as preoperative treatment, and it may also be used in combination with X-ray treatment.

MYXŒDEMA

(*Cachexia strumipriva*)

Myxœdema and cretinism are the results of disease of the thyroid gland, causing deficiency of its secretion—hypothyroidism; cretinism is congenital; myxœdema arises sometimes in childhood (juvenile myxœdema), but more commonly in later life.

Ætiology. Myxœdema is much more frequent in women than in men; and, in the majority of cases, the symptoms begin between the ages of thirty and fifty, though they have begun as early as eight and a half and as late as sixty-seven. Some indications of heredity have been observed, and it has been more often seen amongst the poorer classes. All types of hypothyroidism are common in districts where goitre is endemic.

Morbid Anatomy. The changes in the skin are some nuclear proliferation and development of connective tissue in the neighbourhood of the sweat glands, sebaceous glands, and hair follicles. Gelatinous and œdematous skin, to which

the name *myxœdema* was given by Ord, have only a few times been recorded. There is a fair amount of subcutaneous fat.

The thyroid body is usually reduced to one-half or one-third of its normal size ; it is pale, yellowish white or buff-coloured, tough or indurated, fibrous, or structureless. The gland consists mainly of fibrous tissue, with scattered groups of cells, the remains of the vesicles ; and, finally, nothing but dense fibrous tissue is left. The pituitary body has been enlarged, or enlarged and degenerated in some cases ; in a case of the writer's the suprarenals were atrophied. Arteriosclerosis and myocardial degeneration are common. There is a decreased output of calcium.

Symptoms. These are at first insidious, so that in most cases the disease has not been noticed till it has been well developed. The appearance is then characteristic ; the face is expressionless, not unlike paralysis agitans ; the nose, eyelids, and lips are puffy ; the skin of the face has a most characteristic fine wrinkling, the colour is markedly yellow with a rather bright red patch on each cheek, and almost livid lips. The skin of the body generally is thickened, and the legs and feet have the appearance of slight œdema, although in many cases, but not in all, pitting is entirely absent. The shape of the hand also undergoes changes : it becomes broader opposite the heads of the metacarpal bones, and the fingers become thick and uniform in shape ; this change has received the not very distinctive name of "spade-like." The feet are similarly affected. Perspiration is often deficient or absent, the skin dry and scaly, and the hair falls out, leaving only a thin covering on the head, or causing actual baldness of the scalp ("frontal alopecia" and "cassowary neck"), the outer third of the eyebrows ("eyebrow sign"), and eyelids. The nails are stunted and brittle. The mucous membranes show the same change ; at any rate, the uvula and soft palate are swollen, and the tongue is large and thick ; moreover, the teeth become carious or loose. The nervous system of the patient is the next thing that strikes one : she appears dull, apathetic, and slow in thought and movement, and is often deaf. She speaks languidly and deliberately, as if the thick tongue mechanically interfered with articulation, but the slow movements of the eyes and the muscles of expression accompanying speech indicate that the neuro-muscular apparatus is also faulty. The voice is low-pitched and husky, from swelling of the vocal cords. On the mental side, memory is defective ; the patient is often irritable, or suspicious, or dull and sleepy ; and hallucinations, delusions, and convulsions have been noticed in a certain proportion of cases. Complaint may be made of headache and rheumatic pains. Tetany sometimes occurs, as it does after the operative removal of the thyroid. The temperature is mostly subnormal, the patient suffers from cold very readily, and the hands and feet are often cold and blue.

The pulse is weak or slow ; in advanced cases there is cardio-vascular disease with absent or inverted T waves and a low voltage electrocardiogram and arteriosclerosis ; the urine often contains albumin. Examination of the blood shows a microcytic anæmia. The bowels are constipated. The tolerance for sugar is increased, so that large quantities, even up to 10 ounces in some cases, can be taken without any glucose appearing in the urine. In females menorrhagia is common ; more rarely there is amenorrhœa. Epistaxis, hæmorrhage from the gums and hæmorrhoids are not uncommon. On palpation the thyroid gland is usually small and the rings of the trachea are palpable below the cricoid, where the isthmus should be. The progress of the case is slow ; patients are known to have had the disease ten years or more without material change. Nevertheless, it undoubtedly shortens life ; the sufferers die from myocardial and arteriosclerotic changes or from intercurrent diseases, such as pneumonia and bronchitis, or sink from general or nervous exhaustion.

Diagnosis. Myxœdema is most often confused with Bright's disease, or myocardial degeneration ; but though there may be a little albuminuria, the

renal function is normal. The abnormalities in the electrocardiogram disappear with treatment, which is helpful in diagnosis. Conclusive evidence may be obtained from a basal metabolism test, which may be 40 per cent. too low in a very severe case.

Treatment. Thyroideum (B.P.) made from the dried gland in doses of 1 to 5 grains in cachet or pill may be given by mouth once or twice daily. Synthetic thyroxin may also be given by mouth, the smallest daily dose being 0.2 mgm. In very severe cases of myxœdema oral treatment is not always successful, possibly because absorption from the alimentary tract is so slow. Intravenous injection of a specially prepared solution of thyroxin may be tried, *i.e.* three 5 mgm. doses at weekly intervals. However, it is safer to begin with an injection of 1 or 2 mgm., since severe reactions may be met with twenty-four hours after the administration; the symptoms are rapid pulse, headache, tremors, nausea, vomiting or diarrhœa, and pains in the back and legs. 3:5 di-iodothyronine, a substance allied chemically to thyroxine, and more soluble, has been used with success (51). The treatment should be controlled with the basal metabolism test. When the store of thyroxin in the body has once been increased to the right amount by this means, administration may be continued by mouth. In whatever way thyroid is administered it is advisable to begin with small doses; otherwise anginal symptoms may be precipitated.

CRETINISM

Cretinism is seen as an *endemic* disease in the mountainous parts of Europe (Switzerland, North Italy, and Savoy) and in Northern India (Chitral and Gilgit), where goitre also is extremely prevalent. The two conditions are often associated in the same individual; indeed, many of these cretins are goitrous; of 208 cretins in India, McCarrison found eighty-eight to be goitrous.

Sporadic cretinism occurs in other parts, *e.g.* in England; in the subjects of it the thyroid is deficient, or there is a slight goitre.

Pathology. The association of endemic cretinism with goitre in the individual and in the community, the absence of the thyroid in some cases, and the resemblance to myxœdema, show the relations of the disease to the thyroid gland. When endemic cretinism and goitre appear in the same individual, the former precedes the latter, and so is not due to it. The cretinism is due to the goitrous condition of one or both parents, and the defective thyroid function in the mother acts prejudicially in the foetus. The lesion involves the parathyroid as well as the thyroid bodies.

Symptoms. Cretinism is characterised by stunted growth, a large, broad head, thick features, wide separation of the eyes, flat nose, large mouth, much wrinkling of the coarse and rough skin even in early life, a narrow chest, full abdomen, usually an umbilical hernia, crooked legs, and considerable mental deficiency, amounting to idiocy.

The characteristic features are generally noticed in the latter half of the first year of life; walking is acquired very late, and the arrest of growth may be such that an adult cretin is not taller than a child of five or six. Puberty is long delayed, or the sexual functions are entirely absent. Speech is acquired very slowly or not at all, and some are deaf mutes and idiots. Nystagmus, strabismus and spastic rigidity of the legs occur in some cases. Above the clavicles are often found subcutaneous tumours formed of masses of fat. Remarkable defects are present in the osseous system; the basi-occipital and basi-sphenoid are prematurely ossified; the long bones are permanently shorter than normal, the legs are bowed, and fibrous tissue from the periosteum grows in between the epiphysis and the shaft of the bone. The centres of ossification of the bones of the foot and wrist appear very late. Radiographic examination of these structures affords a valuable means of diagnosis.

Treatment. In cretinism, as in myxœdema, thyroid extract has been

used with much success. Under its influence children have grown rapidly, have lost the cedematous infiltration of the tissues, and have become more intelligent. It must, however, be admitted that the child improves physically more readily than he improves mentally, especially when treatment is begun late.

THE PARATHYROID GLANDS

The parathyroid glands are small bodies, generally four in number, situated near or within the substance of the thyroid, and consisting of groups of epithelioid cells in a fibrous meshwork, but without the vesicular arrangement and colloid contents of the thyroid; each measures 6 or 7 mm. by 3 or 4 mm. by $1\frac{1}{2}$ or 2 mm., and weighs about $\frac{1}{2}$ grain. *Parathormone*, the active principle of the glands, can be obtained commercially. Injection at first causes an increased output of phosphorus in the urine with a fall in the inorganic phosphorus of the plasma; then there is an increase of calcium in the blood, *hyper-calcæmia*; at a certain critical level of serum calcium the blood phosphorus suddenly rises, presumably due to altered renal function, as the non-protein nitrogen of the blood rises as well. Severe hyper-calcæmia causes definite symptoms in dogs; but man is not so sensitive. Parathyroid has been used in many varieties of ill health, infections, etc., in which the amount of ionised calcium in the serum has been found low (*see Chorea*). Unfortunately the action of parathormone is variable and immunity to the drug often develops, so that it is no longer effective (21).

Changes in the parathyroids—hyperplasia, fatty degeneration, fibrosis, cyst and colloid formation—may occur.

Hyperparathyroidism. Hyperplasia of a gland may form a tumour in the neck palpable on swallowing. The serum calcium is raised up to 16–17 mgm. per cent., the plasma phosphatase is high and calcium is lost in the urine daily; the blood phosphate is always low. The calcium comes from the bones, and gives rise to the disease known as *generalised osteitis fibrosa of von Recklinghausen*. This disease is twice as common in women as men.

Symptoms. There is pain in the bones and X-ray examination shows a mottled appearance due to spaces (*osteoclastoma*) diffusely spread through the bones, which may give rise to spontaneous fractures; there may be thirst, polyuria, renal calculi with colic, hypotonicity of the muscles, nausea, vomiting and wasting, which is common in severe cases. Improvement sets in after excision of the tumour; but tetany very commonly results from a rapid fall of blood calcium. This may be relieved by parathormone, which should always be kept available for use (21). Deep X-rays might be an alternative to operation. In the commoner *focal osteitis fibrosa* there is no abnormality in the calcium metabolism.

TETANY

Tetany may arise from disease of the parathyroids, in *spontaneous hypoparathyroidism*, but this is rare. Post-operative tetany after removal of the parathyroids in thyroid operations is well known; but there are many other causes of clinical tetany.

Ætiology. It occurs at all ages, but is especially frequent in infants and young adults. In children males are more often attacked than females; in older people the reverse holds good. In children rickets and diarrhoea are the commonest predisposing causes; in adults the causes are pregnancy and lactation, recovery from febrile diseases, the existence of dilatation of the stomach and intestinal obstruction and, in the case of the writer's, gastro-colic fistula with loss of free HCl in the stools. It has occurred after the operative removal of the thyroid body when the parathyroids have been removed as well. McCarrison says it is common in women in the high valleys of Gilgit (Northern India), and that all such sufferers are goitrous. In these cases it may be due to associated parathyroid disease. Similar paroxysms have been seen as the result of ergotism

and in association with osteomalacia, and from poisoning with sodium bicarbonate. Tetany is sometimes present in certain nervous diseases, particularly in epilepsy. Tetany also occurs in epidemics among workmen at certain seasons of the year, in particular European cities (Vienna, Heidelberg). It may be produced artificially by continued forced breathing, with washing out of CO_2 from the body (*acapnia*).

Pathology. The essential characteristic of the disease is over-excitability of the peripheral motor neuron, and it has been suggested that want of oxygen is the primary cause and that a number of agencies may bring this about (26); thus, *alkalæmia*, due to injections of sodium bicarbonate, or to forced breathing (which washes out CO_2 from the body), may act by rendering more difficult the dissociation of oxygen from oxy-hæmoglobin (pleonexy), so that the tissue oxygen tension falls; the latter also occurs with guanidine and histamine poisoning, both causes of tetany. Parathyroidectomy does not itself cause a lowered O_2 tension, though it is possible that owing to the low blood calcium the oxygen supply to the cells is interfered with. Such interference is known to occur in cyanide poisoning. Another way of producing experimental tetany is by repeatedly washing out the stomach of a dog whose pylorus has been obstructed. The tetany can be stopped by administering sodium chloride intravenously. It is thus possible to group together the tetany of dilated stomach, intestinal obstruction, and gastro-colic fistula as due to a loss of chloride from the body, and in these cases the plasma chloride has been found to be low and the plasma bicarbonate raised, and there is also an increase of urea in the blood. The tetany is not due to alkalæmia in these cases (33), and here again it may be due to a low ionic calcium (24); *i.e.* in hysterical hyperpnœa a low calcium has been found in the cerebro-spinal fluid.

Symptoms. There may be some discomfort or malaise, or stiffness in the arms, or tingling for some hours or days before the attack. Sometimes the paroxysm comes on suddenly without warning. The hands are then bent on the wrist; the fingers are flexed at the metacarpo-phalangeal joints, extended at the phalangeal joints, and pressed closely together with the thumbs bent into the palm of the hands, so that the fingers form a cone ("*main d'accoucheur*"). The elbows are slightly flexed, and the arms are adducted to the sides. Sometimes the four fingers are flexed into the hand, the wrists extended, and the elbows fully flexed. In the lower extremities, the foot is extended on the leg, the tarsus arched, and the toes flexed and crowded together. These are the characteristic contractions, and in most cases these alone occur. In very severe cases spasm affects the muscles of the abdomen, chest, face and tongue, as well as those of the back, causing slight opisthotonus, and of the eyes, causing strabismus. There may be some cramp-like pain in the parts affected; the back of the hands may be tumid, and the veins swollen. There may be sweating, flushing, and slight rise of temperature. The spasm ceases in from five to fifteen minutes, or it lasts one, two or more hours; it gradually subsides, and recurs after an interval of some hours or days.

In the intervals the nerves and muscles show an increased susceptibility to mechanical irritation (Chvostek). Percussion of the nerves causes contractions in the corresponding muscles, and this is well shown in the face by percussing midway between the zygoma and the angle of the mouth. Stroking the face from above downwards causes contraction of the muscles one after the other. Trousseau first showed that in the intervals a fresh paroxysm could be brought on in a few minutes by firmly grasping the arms, or by pressure on the nerves and arteries. The motor nerves also are unduly susceptible to faradism, and still more to galvanism (Erb). Hyperexcitability, suggestive of tetany, exists if galvanic currents below 2 milliamperes produce a contraction on cathodal closing or anodal opening (*see p. 628*). The normal range is between 2.5 and 3.0 milliamperes.

But there is not always an interval between the paroxysms. In infants a continuous spasm is more common, and in adults the spasm may not entirely relax, so that this form is called *remittent*, while the form with complete intervals is called *intermittent*. In *latent* tetany, which is fairly common, there are no spontaneous attacks of spasm.

In rachitic children the undue excitability of the nervous system is represented not only by tetany, but also by laryngismus stridulus, and by convulsions.

In parathyroid tetany lens opacities, which in the earlier stages may be demonstrated by the slit lamp, brittleness and ridging of the nails, transverse ridging of the teeth from defective enamel, and loss of hair may occur (21).

The disease lasts from a few days to a few weeks, and recovery is the rule. Occasionally some weakness of the legs remains for a short time after recovery, and muscular atrophy and fibrillary tremors have been seen. But death may occur from exhaustion when the paroxysms are severe, or from pneumonia as a result of interference with respiration, or in infants from the diarrhoea which caused the disease.

Diagnosis. The distribution of the spasms—namely, their occurrence chiefly in the hands and arms—distinguishes it from *tetanus*. *Hysterical* contractions may assume the form of tetany; they are generally unilateral, and are associated with other hysterical conditions. Latent tetany can be diagnosed by Chvostek's and Trousseau's signs, and by the presence of certain symptoms commonly associated with it, viz., defects in the enamel of the teeth, perinuclear cataracts, dystrophies of the hair and nails and recurring conjunctivitis.

Treatment. Parathormone may be given subcutaneously, intramuscularly or intravenously in doses of 10 to 30 units a day; vomiting is the first symptom of an overdose. Calcium chloride (15–20 grains, in the case of infants) is given by mouth every four hours (25). The chlorine passes into the circulation to supply the deficiency of chloride, while the calcium is excreted by the bowels. Ammonium chloride in large doses may also be tried. The ammonia is converted into urea, so that here also the hydrochloric acid may be utilised. These drugs may also be given per rectum. The predisposing condition of the patient should be as far as possible removed. Thus gastric dilatation should be treated by surgical operation (gastro-jejunostomy); in children, diarrhoea should be treated, and rickets met by cod-liver oil, iron, suitable diet, etc.; women should give up nursing their children, and should take iron and other tonics.

THE THYMUS GLAND

The thymus gland weighs about $\frac{1}{2}$ per cent. of the body weight from birth to 1 year, and diminishes to 0.085 per cent. of the weight between 11 and 16 years. Even in adult life, however, its remnant can be found if carefully sought, consisting of fibrous and fatty tissue, islets of lymphocytes, and a few Hassall's corpuscles (Dudgeon). In atrophy, which is associated with marasmus or tuberculous and other chronic wasting diseases in children, the organ is reduced in size. Enlargement of the thymus may occur in a number of diseases, of which the most important are leukæmia, especially the lymphatic form, Hodgkin's disease, exophthalmic goitre and myasthenia gravis. The gland may be converted into a fibro-caseous mass as a result of tubercle, and it may be the subject of new growth.

In the past importance has been attributed to the thymus as the cause of sudden death in the condition known as *status thymo-lymphaticus*. This diagnosis has been made to account for a death under an anæsthetic, particularly in a child, when the cause of death was not obvious. In these cases there is often a general hyperplasia of the lymphatic structures throughout the body, while the thymus has been considered large. On the other hand the lymphoid tissue is probably no larger in amount than is present in any normal child, though in a

child who has died of any wasting disease the lymphatic tissue shows in the atrophy. A recent investigation has now pointed to the thymus gland as also being within normal limits, so that the diagnosis of status thymo-lymphaticus or *status lymphaticus* has no foundation in fact, and in future such deaths must be attributed to the anæsthetic directly, or in other cases of sudden death to an unknown cause.

THE SUPRARENAL CAPSULES

The suprarenal capsules consist of two parts :—

1. The *cortex* (*interrenal system*) is derived from mesodermal cells closely related to the cells of the genital organs. It contains cholesterin esters and lecithin in large quantity, and its yellow colour is due to these. It is about 90 per cent. of the whole gland in weight, and becomes rather larger during pregnancy. The lipoids of the cortex disappear within a few days as the result of an acute febrile illness of an infective character, which is fatal. On the other hand, they are not discharged in cases of inanition, *e.g.* in malignant disease. In these respects they offer a marked contrast to the ordinary body fat. The cortex is related to sex. In rare cases, where the cortex is hypertrophied, there is precocious development of the sexual organs, with an increase of male characteristics. More commonly these symptoms are caused by carcinoma of the cortex (*q.v.*). Conversely, hypoplasia of the adrenals has sometimes been seen in cases of disappearance or original absence of hair from the genitals and hypoplasia of the genital organs. The cortex contains a reducing substance, hexuronic acid or ascorbic, identical with vitamin C (*q.v.*), which inhibits the *oxidases* of the body. When the reducing substance is absent, as in Addison's disease, the oxidases have full play in converting the hydroquinone groupings in the constituent molecules of the body into the darkly coloured quinone groupings and so pigment the body (27); it is by oxidation that a freshly sliced apple goes dark on exposure to air. Finally, the cortex contains a specific substance which prevents Addison's disease, known as suprarenal cortical extract, eschatin, eucortone or cortin.

2. The *medulla* is derived from the same cells as the ganglion cells of the sympathetic nervous system. It has a characteristic staining reaction with bichromate, and so is called a *chromaffine body*. It elaborates a substance, *adrenin* or *epinephrin*, which has been prepared synthetically, and is chemically ortho-dioxyphenyl-ethanol-methylamine. This substance is poured out into the circulation on stimulation of the splanchnic nerves. It has a powerful action on all sympathetic nerve endings. Under normal circumstances this liberation into the circulation occurs when the powerful emotions of excitement, pain, fear and rage are produced; the processes associated with digestion and reproduction are inhibited; the animal becomes prepared for battle or for flight. The pupils are dilated; the skin becomes pale; the hairs stand on end; the heart is accelerated. The sugar in the blood is increased by action on the liver; the skeletal muscles show increased power and are less readily fatigued. The coagulability of the blood is increased, which is of advantage in case the animal is wounded. There can be little doubt that the proverbial strength of the madman is due to the outpouring of adrenin, while his keepers, who experience his power, are not actuated by the same strong emotions. In dementia præcox it has been found that the medulla is deficient and shows histological changes (28).

It has been suggested that the regulation of the heat produced in the body is largely due to the supply of adrenin acting on the liver, and mobilising glycogen, and that fever results from the rapid liberation of adrenin. On this hypothesis the sudden hyperpyrexia associated with intense congestion of a hæmorrhage into the medulla is a symptom of acute *hyper-adrenalism* (15). Such hæmorrhages are not uncommonly due to specific fevers such as malaria, pneumonia, erysipelas, purpura, etc., where congestion of the medulla might be expected; but hæmorrhage may also result from thrombosis of the adrenal veins; and so in this case the

pyrexia is not due to infection at all, but to sympathetic stimulation ; it is a "sympathetic fever."

In some of these cases the fever may subside, and be followed by a subnormal temperature, asthenia and collapse—symptoms of acute *hypo-adrenalism* because the medulla has been destroyed. In this connection it is to be noted that in persons dying slowly with general distress the adrenalin content of the medulla will be found to be from 0·2 milligramme to 2·3 milligrammes, whereas in cases of sudden death the amount is about 4·5 milligrammes. Other symptoms of acute *hypo-adrenalism* are sudden onset of epigastric pain and tenderness, followed by abdominal distension ; convulsions, coma and delirium, or a typhoid stage.

ADDISON'S DISEASE

This disease was first described by Dr. Thomas Addison in 1855.

Ætiology. The disease may occur at all ages, and is commoner in males. Tuberculosis is the most frequent cause. In some cases the capsules become infected from pre-existing phthisis, or spinal caries or psoas abscess ; but in many cases it is a primary tuberculous infection of the glands. On section they show a combination of translucent greyish or greenish-grey tissue and opaque yellow cheesy substance. Sometimes the caseous matter has softened down into a cavity containing pus. In 25 per cent. of cases the only change is atrophy of the cortex (29). In other instances the glands have been attacked by growth, or there has been thrombosis of vessels with extravasation of blood.

Pathology. Addison's disease is due to destruction of the cortex of the suprarenal, so that there is absence of ascorbic acid with resulting pigmentation as already explained. The absence of the specific cortical substance leads to a fall in the sodium chloride of the plasma, a rise in the potassium, and a renal retention of nitrogenous substances ; the kidneys still excrete plenty of chloride and excess of water. These biochemical changes cause polycythæmia from concentration of the blood, the low blood pressure and general asthenia of the disease, and possibly the gastro-intestinal disturbances. The basal metabolism has been found below normal (4).

Symptoms. The cardinal symptoms are debility, low blood pressure, vomiting and pigmentation. The onset is generally insidious, and the patient gradually suffers from weakness, depression, languor and indisposition for exertion. There may be pain and tenderness in the loins, hypochondrium or epigastrium. The heart's action is very weak, and there are faintness and giddiness on rising in bed, or breathlessness and palpitation on exertion. The pulse beats from eighty to ninety in the minute, and is small and feeble ; the blood pressure is very low, measuring as little as 80 or 60 mm. of mercury. Appetite is generally deficient, and nausea, retching and vomiting are important features of the disease. A crisis is marked by diuresis with concentration of the blood and so polycythæmia. Irritability and restlessness are sometimes very pronounced. A peculiar *discoloration of the skin* is the symptom which has attracted most attention. This symptom may be noticed coincidentally with the above general symptoms ; it may develop before them, or it may occur several months after they are pronounced. It is possible, in this last class of cases, that, if the general symptoms are very severe, they may be fatal before the skin is affected ; and thus the occasional absence of pigmentation in Addison's disease of the suprarenal capsules is explained. The pigmentation or *bronzing* is, in its lighter shades, dusky or yellowish brown, sometimes of olive or greenish-brown hue. In its more pronounced form the skin has a rich brown colour, like that of a mulatto. The pigmentation usually affects, first, the parts of the skin which are naturally exposed, such as the face, neck and the backs of the hands and fingers, and not the scalp or the lip under the moustache ; secondly, parts which are naturally more deeply pigmented than others, such as the axillæ, penis, scrotum and areolæ of the nipples ; and thirdly, seats of pressure or slight injury, such as the marks of

garters and waistbands in women, and places where blisters and plasters have been applied. But the scars of wounds destroying the skin remain white, and are bordered by a deep layer of pigment. Sometimes there is darkening of the depressed lines in the palms. On the darkened parts of the skin may be seen small black specks, like moles or freckles. In advanced conditions the whole body may be covered by the pigmentation; but, as a rule, one must be prepared to recognise the disease, and, indeed, many patients die before this stage is reached. The pigmentation is not limited to the skin. A bluish-black line may often be seen on the inner side of each lip running along the mucous membrane, parallel to the line of junction with the skin; and other more irregular patches may occur on the mucous membrane of the cheek and on the side of the tongue. Some of these seem to be determined by the presence and consequent irritation of carious teeth. The temperature is, as a rule, normal; the urine is normal. Although weak, the patient is not necessarily emaciated; even a considerable layer of subcutaneous fat may persist to the end.

The course of the disease is very variable. It is often marked by exacerbations and remissions, periods of severe illness, which confine the patient to bed, alternating with times of comparative health; but after each fresh aggravation of the disease the patient is left decidedly worse than he was before it. The duration varies from a few months to six or seven years. Death takes place mostly by asthenia, the patient getting gradually weaker and lapsing into a drowsy or semi-comatose condition, with increasing feebleness of pulse. Delirium and convulsions occasionally close the scene. In some cases the general symptoms and a very slight pigmentation have been noticed only for some months, when extreme prostration has ensued and carried off the patient in a few weeks.

Diagnosis. The mistakes most likely to be made are: (1) to take some other discoloration for that of Addison's disease; (2) to fail in recognising the symptoms when the pigmentation is slight or absent. The discolorations likely to be mistaken for it are slight *jaundice*, or that of *pernicious anæmia*; *phtheiriasis*, to be recognised by the scratches and the limitation of the colour to parts which can be reached by the finger nails, and the entire freedom of the face; the sallow or earthy tints of *malaria* and of *phthisis*; *chloasma uterinum* in women; and *tinea versicolor*. In early stages, without much darkening, the apparently causeless weakness, with small, feeble pulse, and sickness, are the diagnostic features. The biochemical and therapeutic tests are the most certain. The symptoms will be aggravated by a salt-free diet (but this is not free from danger) and improved by giving salt and abolished by cortical extract; the latter raises the plasma chloride and abolishes the other abnormal biochemical changes.

Treatment. This affords one of the striking recent advances in medicine. Salt in doses of 10 or 15 grams a day ameliorates the disease. Daily subcutaneous injections of cortin up to 10 c.c. completely remove the symptoms with disappearance of pigmentation. This expensive drug can be dispensed with to a large extent if salt is given; the pigmentation disappears on giving ascorbic acid (*q.v.*).

TUMOURS OF THE SUPRARENAL CAPSULES

The tumours affecting these glands are adenoma, sarcoma, carcinoma and neuroblastoma. Sarcoma is very rare, and occurs only in adults. Neuroblastoma occurs in children, and arises from the medulla of the gland. It is a malignant growth, closely resembling a small-celled sarcoma, but it has rosettes, which are characteristic of neoplasms of the central nervous system. It readily gives rise to secondary deposits in the bones. It may form a large mass, which may be mistaken for a renal tumour; it is likely to be fatal, unless it can be removed early. Carcinoma is rarely primary, but generally part of widespread secondary lesions. When primary, it is a small-celled carcinoma, which very readily gives rise to hæmorrhage and necrosis. The cells have a tubular or alveolar arrange-

ment, or are grouped radially round blood vessels ; and there is a general resemblance to the suprarenal cortex. Metastasis may occur in different parts of the body. When present, the growth gives rise to characteristic symptoms due to the activity of the tumour cells (hyper-interrenopathy). The same symptoms are observed with simple hypertrophy of the cortex. If the disorder begins in intrauterine life *female pseudo-hermaphroditism* is seen ; i.e. the individual is in reality female, as ovaries are present, but has external male characters. This condition is congenital, and is due usually to bilateral cortical hyperplasia. When the disease begins soon after birth, it produces the condition known as *premature puberty*. The children become obese. In male children there is precocious and excessive sexual development. Great muscular strength is developed, producing what is known as the *infantile Hercules* type ; there are hair on the face and increased sexual functions. Occasionally feminisation or homosexual precocity occurs. In girls there is usually masculinisation, or heterosexual precocity with hypertrophy of the clitoris, growth of hair and deepening of the voice ; but homosexual precocity has also been described, and there may be early menstruation. In later life hyper-interrenopathy leads to *adult hirsutism* or *virilism*. In women certain male characteristics are seen. Hair grows on the face, and the hair elsewhere on the body is increased ; there is absence of menstruation and of mammary development ; there is increased bodily strength and mental symptoms suggestive of masculinity, such as aggressiveness and egotism, appear. In the case of *progeria* or premature senility, shown in Plate 38, there are bilateral tumours in the suprarenal areas and no evidence of pituitary involvement as found in other cases ; the arteries are thickened, and blood pressure, blood urea and sugar raised and the patient is bright and fond of games with other children.

Certain other changes in the suprarenal capsules may be mentioned. Inflammation and *abscess* from proximity to suppurating foci, hæmorrhage from injury, *lardaceous* change in common with other organs, miliary tubercles in general tuberculosis, and rarely syphilitic gumma, are among the other pathological conditions which may be found.

THE PITUITARY GLAND

This gland, often called the hypophysis, consists of three parts :—(1) the *pars anterior* or *glandulosa*, derived from the buccal ectoderm and containing colloid cysts ; (2) the *pars posterior* or *nervosa*, consisting of neuroglia fibres and cells ; (3) the *pars intermedia*, glandular in structure, lying between the first two. The colloid from the *pars anterior* (anterior lobe) is discharged through the *pars posterior* (posterior lobe) into the third ventricle, and is found in the cerebro-spinal fluid.

Pathology. Experimentally, in rats it has been found that removal of the anterior lobe prevents both the general growth of the animal and the development of the sexual organs (*hypopituitarism*). Again, the injection of active extracts causes gigantism. In man over-activity of the anterior lobe (*hyperpituitarism*) leads to *gigantism* in early life from overgrowth of the long bones, and in adult life to *acromegaly*, when the epiphyses of the long bones have finally become ossified. In both cases the overgrowth is associated with hyperplasia of the thyroid and parathyroid and of the adrenal cortex ; and it not only involves the bones but all the structures in the body, so that *macrosomia* would be a better term to employ. Recent work has proved the importance of the anterior lobe as a regulator of all types of endocrine activity, as well as of carbohydrate metabolism (see hypoglycæmia). If the anterior lobe of the pituitary is destroyed, degenerative changes occur in the thyroid, ovaries, testes, pancreas, suprarenal cortex and possibly the parathyroids ; these can be prevented by the injection of anterior pituitary extracts, from which thyrotropic, gonadotropic (see Gonads)

and adrenotropic hormones have been prepared, as well as a hormone which stimulates the breast to secrete milk; these hormones are normally liberated from the anterior lobe into the body and control the other endocrine organs. For instance, the thyrotropic hormone stimulates the thyroid to secrete thyroxin and so raises the basal metabolism; but this rise does not last because, in spite of continued activity of the gland, the body produces some anti-thyrotropic substance (40). The endocrine relationships of the pituitary are thus complicated, and lesions may produce various pluriglandular syndromes depending on which particular hormone is missing. A scheme is shown below.

ANTERIOR PITUITARY HORMONES.

Thyrotropic, stimulates thyroid gland, raises basal metabolism. ? to pancreas. ? parathyrotropic	Adrenotropic, stimulates adrenal cortex. to breast, stimulates production of milk.	Gonadotropic, (a) a prolactin-like substance, which stimulates ovary to produce (1) oestrogen. (2) progesterone. (b) stimulates testis.
--	---	--

From the pars posterior is obtained an extract (pituitrin) which contains two hormones *vasopressin* (*pitressin*) and *oxytocin* (*pitocin*). It is possible that these are normally discharged with the colloid into the cerebrospinal fluid. Oxytocin has a direct action on the uterus. Vasopressin stimulates the intestinal muscle and also causes a rise of blood pressure with diuresis in the anaesthetised animal, and an increased flow of cerebrospinal fluid and milk; but in an unanaesthetised man the volume of urine is diminished. The pars posterior also provides a substance necessary for the growth of oxyntic cells in the stomach and of the marrow. Injection of large doses in rabbits causes hæmorrhagic gastritis, which begins in the oxyntic cells.

The adiposity often met with in pituitary disease is due to pressure on the hypothalamic region; diabetes insipidus is considered later.

Morbid Anatomy. Pituitary disease may be due to: (1) Lesions inside the sella turcica (*intrasellar*). Of these there are: (a) the *eosinophilic adenoma*, consisting of the proper secreting cells of the anterior lobe; this causes hyperpituitarism: (b) the actively growing *chromophobe adenoma*, the cells of which do not contain granules that stain with eosin; this tumour tends to destroy the anterior lobe and so causes hypopituitarism: (c) the *mixed adenoma* with both eosinophilic and chromophobe elements; this gives rise to *dyspituitarism*, a condition in which signs of both hyper- and hypo-pituitarism are present simultaneously; these adenomas do not usually occur in people under twenty years: (d) the rare *adeno-carcinoma*: (e) ischæmic necrosis from infarction: (f) the recently discovered basophil adenoma with its characteristic symptomatology. It is remarkable that while adenoma occurs in about 10 per cent. of autopsies, especially in later life, it is present in 50 per cent. of cases where there is a neoplasm in other parts of the body (37). (2) *Suprasellar* lesions, which are all destructive and so cause hypopituitarism. Of these the suprasellar cyst is the commonest; it is described under Cerebral Tumour. Other growths are meningioma, cholesteatoma, glioma, and sarcoma: (3) Intracranial lesions at a distance, which cause a secondary hydrocephalus and so cause pressure on the pituitary from above.

Symptoms. These depend on variations in the activity of the gland caused by the lesion (glandular symptoms) and on pressure on surrounding structures (neighbourhood symptoms). The latter are described under cerebral tumour.

Hypopituitarism may be associated with symptoms of a distant cerebral lesion.

Glandular Symptoms. *Acromegaly.* This is due to hyperpituitarism. The disease was described by Marie in 1880. It usually occurs in adolescence or early adult life. There is enlargement of the bones of the extremities (hands

and feet) and of the face (ἄκρον, an extremity; μέγας, large). The phalanges are thickened, and there are bony exostoses. The jaw is enlarged and is undershot (*mandibular prognathism*). The teeth become separated. The soft parts are also thickened; the papillæ of the skin are hypertrophied; the nails are broad, coarse and ribbed; the skin is thick and greasy; and the lips and nose and ears and tongue are coarse and large. The thickening of the fingers gives a characteristic appearance to the hand—*type en large* (Marie). The viscera, including the heart, are enlarged. There may also be kyphosis. Acromegaly with active hyperpituitarism is associated with an increased basal metabolism and a lowered sugar tolerance, so that there is hyperglycæmia and glycosuria if a sugar tolerance test is carried out. True diabetes may occur with ketosis, and in one such case the diabetes was greatly improved after removing the tumour (31). If dyspituitarism supervenes, the sugar tolerance is increased. There is often low intellectual development.

If hyperpituitarism occurs during childhood, the bones become longer than normal (*gigantism*). The fingers also become longer than normal, and the type of hand that results has been called the *type en long* by Marie.

Hypopituitarism. The purest examples are those rare cases where the anterior lobe has been destroyed by infarctions, the result of some septic process. If this occurs in childhood dwarfism results (pituitary *ateleiosis* or the Lorain type of infantilism). The whole body is small (microsomia or *hypophyseal nanism*) but well proportioned; the sexual organs are undeveloped and the secondary sexual characteristics absent. In the type called *Simmonds's disease*, the patient becomes apparently old with wrinkled skin and wasting of the subcutaneous tissues, asthenia, mandibular, dental and genital atrophy, amenorrhœa, anorexia, constipation and *lowered* body temperature, blood pressure, pulse frequency, blood sugar and basal metabolism. He may die in a somnolent state. This premature senility with atrophied viscera may come on in adult life if the anterior lobe is destroyed at this time. Pituitary dwarfism associated with premature senility may be found; this is one type of *progeria*. As may be imagined from the controlling effect of the pituitary on other endocrine glands, which has already been mentioned, when these glands are found to be atrophic, symptoms may be due to a multiple deficiency of hormones—a type of *pluriglandular syndrome*. Of course, neighbourhood symptoms are absent in these cases; but the pituitary fossa may be small in long-standing cases (see Plate 57, B).

The suprasellar tumours commonly produce a combination of adiposity and infantilism met with in children, and known as *Fröhlich's syndrome*, or *hypophyseal dystrophia adiposo-genitalis*, which is due to hypopituitarism. The fat is most noticeable on the abdomen, buttocks, and proximal portions of the extremities. Dwarfism may result. The genital organs remain in an infantile state, and the skin is pale, thin, soft, and smooth. The nails are small, without crescents, and the fingers are tapering. The epiphyses remain unclosed. Mental development is usually normal. The clinical picture due to these tumours is often not clear cut; there may be emaciation, polyuria and premature senility.

The chromophobe adenoma of the adult produces at an early stage depression of sexual functions, which is indicated in the female by amenorrhœa. The cutaneous changes may be seen as just described, and there is a tendency to adiposity and loss of hair and pigmentation. There may also be asthenia, drowsiness, increased sugar tolerance and subnormal temperature from lowered metabolism, and in some cases polyuria.

Basophil Adenoma of the Anterior Pituitary or Cushing's Syndrome. The constant symptoms of this syndrome are painful adiposity confined to the face, trunk and neck, rounded shoulders or kyphosis, loss of sexual function, including amenorrhœa, increase of hair on face and trunk in the female and young male, a *plethoric appearance* of the skin with dusky lineæ atrophicæ, vascular hypertension, polycythæmia, backache, abdominal pain and asthenia. The variable

symptoms are blueness and œdema of extremities, ecchymoses like bruises, various eye symptoms, dryness of the skin, thirst and polyuria, polymorphonuclear leucocytosis, glycosuria, osteoporosis and spontaneous fractures. At autopsy there may be chronic nephritis, colloid goitre, cortical hyperplasia of the suprarenals, atrophy of the gonads, so that the symptomatology evidently represents a pluriglandular syndrome, and it has in fact been found in cases of carcinoma of the suprarenal cortex.

In adults cases of extreme obesity may be due to pituitary disease. *Adiposis dolorosa*, or *Dercum's disease* may probably be either due to pituitary disease or hypothyroidism (see p. 501). Epilepsy is also associated with hypopituitarism.

Diagnosis. This depends upon the recognition of neighbourhood and glandular symptoms, and is usually not difficult. However, it is important to distinguish between intrasellar and suprasellar lesions and intracranial lesions at a distance, which cause pituitary symptoms. The age incidence of adenoma and suprasellar cyst will be of value in distinguishing the first two, and there are also the characteristic X-ray appearances and the different symptomatology. The intracranial lesion at a distance, such as a cerebellar tumour, will also provide characteristic signs.

Prognosis. This is bad, since the tumour usually progresses, although slowly. The operative mortality of sellar decompression is about 7 per cent. (Cushing).

Treatment. In cases of hypopituitarism benefit has been obtained by administering the anterior lobe in tablets by the mouth, combined with thyroid. Pituitrin must be given subcutaneously, since it is destroyed by the alimentary canal. The progress of treatment can be estimated from the sugar tolerance. Operative treatment is considered under Cerebral Tumour.

DIABETES INSIPIDUS

Polyuria may be caused by disorders of the kidney, by increased blood pressure, by the presence of sugar in the urine in diabetes mellitus, in severe Addison's disease, and temporarily in some disorders of the brain, especially hysteria and migraine. Diabetes insipidus is a persistent polyuria not traceable to any of the above conditions.

Pathology. Diabetes insipidus may be due to injury or disease of the pituitary gland, probably the posterior lobe. Subcutaneous or intravenous injections of pituitrin (vasopressin) are specific for the disease, the urine being at once reduced to the normal volume, and the patients get complete relief from their symptoms. Motzfeld has shown that in the unanæsthetised animal the volume of urine is diminished, and this diminution is more striking if an artificial polyuria has been produced by previously filling the stomach with water. The action of the drug is stopped if the splanchnic or renal nerves are divided. The action of the extract is probably due to rather more than mere splanchnic vaso-constriction; its presence may be necessary for the reabsorption of water at the end of the tubules (see p. 518). Diabetes insipidus may also follow injury of the hypothalamic region of the brain, possibly because the normal outflow of the pituitrin is obstructed.

Morbid Anatomy. Radiograms of the sella turcica usually show no enlargement. Various lesions of the pituitary gland or its neighbourhood have been described: fractures of the base of the skull, cerebral tumour, syphilitic or tuberculous basal meningitis, caseation of the infundibulum. In one remarkable case a bullet was found pressing against the posterior lobe. Parkes Weber has described what he regards as a tuberculous infiltration of the posterior lobe of the gland.

Dilatation and hypertrophy of the bladder, dilatation of the ureters, and enlargement of the kidneys may be seen, and are attributable to the prolonged pressure of large quantities of urine.

Symptoms. These begin either insidiously or suddenly. The prominent symptoms are the enormous quantity of water passed and the great thirst by which the patient is led to replace the loss. The urine may reach 15, 20 or even 40 pints in the twenty-four hours. It is very pale, almost like water, of specific gravity 1,002 to 1,005, and faintly acid in reaction. The percentage of solid constituents is small. Occasionally there is glycosuria or an increased secretion of the salivary glands. The mouth, tongue and skin are dry, and the bowels constipated. Beyond this the patient may be in the enjoyment of very good health, and he finds the diabetes an annoyance rather than an illness. The symptoms of pituitary disease may also be present.

Spontaneous and idiopathic cases may last for years if untreated. They are rarely fatal, except from the intervention of other illnesses; occasionally glycosuria has supervened, and the case has become one of diabetes mellitus.

Diagnosis. The enormous quantity of pale urine, of low specific gravity without abnormal ingredient, and the accompanying thirst, are distinctive. But care must be taken to exclude other forms of polyuria, such as those from *Brigh's disease* and *hysteria*. In the former there is generally at some time or other a distinct trace of albumin, the quantity of urine is not so considerable, and other indications are present, such as high arterial tension and cardiac hypertrophy. In hysteria the condition is but temporary.

Treatment. This consists in the administration of pituitary extract subcutaneously. One cubic centimetre (15 minims) is injected twice a day to begin with. The attempt is then made to control the volume of urine with as few injections as possible. Unfortunately treatment by the mouth is useless, as the active principle is destroyed in the alimentary canal; but the drug has been given by means of an intranasal spray or a nasal jelly containing pitressin, or best of all by dried pituitary insufflated into the nose as "pituitary snuff." Some cases are refractory to pitressin.

In syphilitic cases antisyphilitic treatment (*q.v.*) is indicated. In cases of gross cerebral disease (*e.g.* tumour, etc.) the question of operation will naturally arise. A few cases have been relieved by lumbar puncture, which suggests that a serous meningitis at the base of the brain was responsible for the disease (32).

THE PINEAL GLAND

The pineal body (epiphysis cerebri or conarium) is a glandular organ, weighing about $3\frac{1}{2}$ grains, and consisting of epithelioid cells in loosely disposed trabeculæ, with blood sinuses between them. Like the thymus, its chief use appears to be in early life, and it undergoes a certain amount of involution later.

The lesions which have been recorded are hypertrophy and atrophy, tumours, cysts and abscess, hæmorrhage and syphilis.

In the cases of tumour which have shown changes in metabolism, indicating a disturbance of the internal secretion, the subjects have been boys up to eleven years, and the changes consisted, in different degrees in different cases, of mental precocity, unusually rapid growth of the body, enlargement of the penis and testes, precocious growth of pubic hair, and sometimes adiposity. These were sometimes associated with evidences of intracranial tumour, and the tumours present were in different cases sarcoma, cystic psammo-sarcoma, glioma or teratoma.

THE GONADS

A systematic description of the pathological changes found in the testicle and ovary will be found in text-books of surgery and gynæcology. The gonads will only be considered here from the point of view of their endocrine function.

Female Sexual Organs. At the beginning of the menstrual cycle, after hæmorrhage has ceased, the mucous membrane of the uterus consists of a single

layer, the basal mucous membrane. During the first half of the cycle it proliferates, becoming thicker under the influence of a hormone, which is called œstrin or the follicular hormone or folliculin; this, the female sex hormone responsible for secondary sexual characters, is produced by the Graafian follicle, which grows to maturity during the same period. After the bursting of this follicle with liberation of the ovum, the corpus luteum is formed and this produces a second ovarian hormone called progesterin, which causes an increase in glandular activity of the uterine mucosa with convolution of the glands—the secretory phase—preparatory to the reception of a fertilised ovum. If conception does not take place the mucous membrane breaks down and becomes discharged from the uterus with hæmorrhage, thus ending the cycle. In castrated females the menstrual cycle can be initiated by giving large doses of dioxy-œstrin (2,500,000 units) in five doses on the first, fourth, seventh, eleventh and fourteenth out of twenty-eight days, followed by progesterin (five rabbit units), *i.e.* one rabbit unit a day, beginning on the seventeenth day (42), so that amenorrhœa due to poor development of the sexual organs may be treated by this means. If too much œstrin is found in the body, or administered, the Graafian follicle continues to grow without bursting, and the mucous membrane also continues to grow and becomes cystic and may eventually break down with severe hæmorrhage. As the corpus luteum is not formed, there is no progesterin to bring about the secretory stage, and this should be administered by injection during the stage of hæmorrhage; often quite small doses are sufficient—three to ten rabbit units spread over five days, though sixty to eighty may be necessary. Œstrin also produces changes in other sex organs, such as the vagina—cornification of the epithelium in the rat and mouse—to facilitate mating. Curiously enough the richest source of naturally occurring œstrin is the urine of the stallion, and the most active compound is obtained by adding two hydrogen atoms to the œstrin molecule, which is a sterol allied chemically to cholesterol and calciferol (vitamin D) as well as to the most active cancer-producing substance which has so far been prepared. Further, a number of different though closely allied substances possess œstrogen-producing properties in varying degree, while one has the power of producing both œstrus when injected and carcinoma if painted on the skin (43). The development of the ovary and all that follows from it is controlled by the anterior lobe of the pituitary, by means of a hormone unnamed at present, which in small amount causes the development of the Graafian follicle with secretion of œstrin, and in large amounts causes full development of the corpus luteum which secretes progesterin. During pregnancy there is present in the blood and urine a closely allied substance which probably arises from the placenta and is called prolactin. This fact was first utilised by Ascheim and Zondek as a means of testing for pregnancy, since the injection into animals of urine containing prolactin produces changes in the ovaries that can be recognised (44).

Male Sexual Organs. Removal of the testes causes non-development or atrophy of the accessory organs, seminal vesicles, prostate, Cowper's glands and penis. The influence exerted by the testes is due to the male sex hormone elaborated in the interstitial cells of the testis. Like the ovary, the development of the testis is also under hormonal control of the anterior pituitary. This gonado-tropic principle, which is present in urine during pregnancy, may be of value in treating undescended testicle, 500 rat units in the form of "pregnyl" being injected twice weekly (45).

Eunuchism. The symptoms depend on whether castration has been performed before or after puberty. In the former case the penis, prostate, vesiculæ seminales, remain small and the subjects do not develop libido or potentia. If the operation is performed after puberty, the penis need not atrophy much, but the prostate becomes smaller. Libido may persist, and even potentia, at least for a time. Prostatic secretion is ejaculated. Psychically, the normal aggressiveness of the

male disappears, but eunuchs may possess great intellectual powers and artistic ability. Physically, they are either (1) tall and thin, with long arms and legs, or (2) short and fat, with a distribution of fat similar to hypophyseal dystrophia genitalis. In both types the pelvis remains broad, the skin pale; there is drooping of the lateral half of the eyelids with a sleepy appearance, and there is generally a deficient growth of hair. In the female, double oöphorectomy brings on a premature menopause with tendency to obesity, hot flushes, respiratory, cardiac, and digestive disturbances. Neurasthenia, psychasthenic or psychotic symptoms may appear.

Eunuchoidism. This term is applied to conditions resulting from loss of the gonads by disease. They are not uncommon in patients with undescended testicles (*cryptorchidism*). Like eunuchism, the condition may be noticeable at puberty (early eunuchoidism) or later during the normal period of active sexual life (late eunuchoidism). As in eunuchism, the patients may be tall or short and fat. Mentally, they are quiet and silent and there are disturbances in libido and potentia. The skin is pale and sometimes has large numbers of small wrinkles. Linear wrinkles radiating from the mouth make these patients look prematurely old. Female eunuchoids are tall, and fat is deposited on the lower abdomen, mons veneris, buttocks and outer sides of the thighs and the mammary glands. The uterus and vagina become hypoplastic.

Hyper and Hypogenitalism. While the terms eunuchism and eunuchoidism are reserved solely for results following primary disease or absence of the gonads, over- or under-activity of the latter may also result secondarily from disease of other ductless glands. Thus hypergenitalism which causes precocity or premature puberty may result from tumours of the testicle or ovary, from hyperfunction of the latter, or from tumours of the suprarenal cortex or pineal body already described. Delayed puberty, so commonly met with in both sexes, may similarly be due to hypofunction of the gonads primarily or may result from other organs acting on the gonads.

VARIED SYNDROMES

OBESITY

Obesity, corpulence, or excessive fatness is a condition which may amount to a disease, and sometimes calls for treatment. But it is often difficult to say where normal deposition of fat ends, and where obesity begins; and the two conditions must be dealt with together.

Ætiology. There appear to be some differences in the tendency to obesity among the races of mankind. Heredity certainly has a share in its occurrence. There are some periods of life when fat is more likely to accumulate; these are infancy, puberty, during pregnancy and at the climacteric in the female, and during middle age in the male. Females, on the whole, are more liable to be fat than males.

Pathology. In a normal individual whose body weight remains constant the energy supplied by the utilisation of the food must balance the energy given out in the form of heat and external muscular work. If he suddenly changes his habits by leading a more sedentary life, the energy output will be diminished, and less food will be oxidised, the excess being deposited in the body as fat. Both fats and carbohydrates are readily stored in this way; but the constituents of protein are more easily oxidised, increasing the heat output. This is called the *specific dynamic action* of protein. Hence the important factors in many cases of obesity are bodily inactivity and over-eating.

There are, however, cases of great obesity which cannot be entirely explained in this way. Amongst healthy persons there are many very fat who eat comparatively little; and, on the other hand, many big eaters are persistently thin.

These idiosyncrasies are explained by the rate of oxidation peculiar to the

INFANTILISM

By infantilism is meant the retention of the characters of childhood for a longer time than usual, or an abnormally slow development. Infantilism is not necessarily associated with dwarfism; but the childish form may be retained, and there may be delayed ossification and absence of sexual development. There need not necessarily be any delay in the child's mental progress.

Infantilism may be secondary to various chronic infections and other toxic causes, such as syphilis, tubercle, malaria, pellagra, scarlet fever, chronic diarrhoea, pancreatic deficiency and some inorganic poisons, such as lead and mercury; chronic interstitial nephritis in children may be associated with infantilism. A second group includes those cases which are due to disease of the endocrine organs, such as cretinism, Fröhlich's syndrome, pituitary ateleiosis, progeria, and diabetes insipidus. Other instances of infantilism are the delays in development which have been seen in association with achondroplasia, muscular atrophy, scleroderma, cardiac and vascular lesions, microcephaly, hydrocephalus, amentia, hypertrophic cirrhosis of the liver, splenomegalic cirrhosis, and some other disorders. Finally, there is the sexual form of ateleiosis, which is of unknown origin and which differs from the pituitary form already described in that ultimately the sexual organs mature, the epiphyses unite, and the individual remains in some respects a child, in others a man or woman in miniature.

APPENDIX

Glycogen Disease (*Hepato-megalia glycogenica* of Von Gierke). In this disease of children, often congenital, there is enlargement of the liver and sometimes of the kidneys, with increased storage of glycogen in these and other organs constituting the main feature. There is a tendency to infantilism and obesity. The fasting blood sugar is low with a delayed fall in the blood sugar tolerance curve; the blood sugar does not rise after injecting adrenaline. The blood glycogen and cholesterol are raised and there is acetonuria.

R. W. B. ELLIS and W. W. PAYNE .. 1936 *Quart. J. Med.*, N.S. 5, p. 31.

DISEASES OF THE URINARY ORGANS

EXAMINATION OF THE KIDNEY AND BLADDER

THE kidney normally extends from the lower border of the eleventh dorsal vertebra to the lower border of the second lumbar vertebra, its inner margin being, on an average, 3 inches from the middle line; and it is fixed in this position by its surrounding capsule of adipose tissue, by the layer of peritoneum in front of this, and by the renal vessels. The position of the kidneys corresponds on the anterior surface of the body to a rectangular figure, 8 inches by 4 inches, having its lower long side level with the umbilicus, and its short sides each 4 inches from the middle line.

The kidney cannot be felt, except in very emaciated persons, or when it is enlarged, or when it is more mobile than normal (*movable kidney*), or when it is pushed down by disease above. Each flank should be examined by the bimanual method, and the patient should be directed to take a deep breath; or in thin persons the flank may be grasped by one hand, the fingers behind and the thumb in front. An enlarged kidney forms a rounded swelling, which fills up the loin when it is palpated from behind, while in front the hand can be inserted between the upper part of the tumour and the costal margin; in these ways it differs from a large liver or large spleen, which also both have their characteristic shapes. Further, if the resonance of the colon is detected in front of the mass, it is not the spleen or the liver. An *ovarian* tumour grows up from below, whereas a renal tumour begins above and grows downward. *Mesenteric glands* lie nearer the middle line than the kidney, and form very nodular masses; isolated enlarged glands may give a clue to the nature of the larger mass.

Uro-Selectan B, an iodine pyridine compound, opaque to X-rays and excreted by the kidney, provides a valuable means of examination. Ampoules contain 15 grams of the dye in 20 c.c. of solution, for an adult, and this is injected intravenously (3); *abrodil* is an alternative preparation. Radiograms are taken before, and three, seven and fifteen minutes after intravenous injection; a lateral radiogram should also be taken. The whole area of each kidney is shown up as a faint shadow and in three minutes an opacity is already visible in the pelvis and by fifteen minutes the whole pelvis with calyces, ureter and bladder can be seen. Hence the shape, position, rate of excretion of the kidney—thus the dye is also a test of renal function—the size, shape and position of the pelvis and ureter, their relation to shadows suggesting calculi, deformation and filling defects due to growths, kinking and hydronephrosis can be determined. If a radiogram is taken in the vertical position the amount of dropping of the kidney can be determined. (Plate 39.)

With the aid of the cystoscope information may sometimes be obtained as to the condition of the kidneys. If one or other kidney is the subject of pyelitis, pyelo-nephritis, tuberculous disease, or similar lesion, and the ureter is involved, the orifice of the ureter in the bladder may be patent, with swollen lips and vascular adjacent mucous membrane. The ureters may be catheterised and the urine from them collected separately in order to find out if disease is localised in one of the kidneys. The relative volume of the urine from each kidney is

noted, and examination for blood, pus and albumin is carried out. In the diagnosis of certain congenital malformations of the kidney, hydronephrosis, kinking of the ureter, renal tumours projecting into the pelvis and renal calculus, *retrograde pyelography* may be of assistance. After catheterising the ureter and allowing urine to escape, a 20 per cent. solution of sodium bromide, which is opaque to the X-rays, is cautiously run in and a radiogram is then taken. The normal pelvis will allow 6 c.c. of the solution to enter. No anæsthetic is given and the injection is stopped if pain in the loin is experienced. Only one ureter is catheterised at a sitting. To show up the bladder 10 per cent. sodium bromide may be used, or 10 per cent. colloidal silver (1) (*see* Plate 40).

EXAMINATION OF THE URINE

Quantity. The water content of the body is a balance between that which is taken in by the mouth and that which is excreted from the kidneys as urine, from the skin as sweat, from the lungs, in the fæces, etc. The secretion of urine depends on the amount of blood flowing through the kidneys. Excessive secretion of urine is called *polyuria*, its suppression *anuria*, which must be distinguished from *retention*. The volume is increased by the ingestion of fluids and exposure of the body to cold, because in the latter case the secretion of sweat is diminished, while it is diminished by abstinence from drink, by free sweating, and the loss of fluid from the circulatory system. The average daily volume of urine is 1,500 c.c.

In disease, variations are seen in the following circumstances: The flow of urine is increased in secondary contracted kidney, in rare cases of cerebral disease, in diabetes insipidus, and in diabetes mellitus. A temporary increase is seen in hysterical attacks, as a result of mere nervous excitement (not infrequent during medical examination for life insurance), and from the administration of substances having a diuretic action, such as the acetates, citrates, and tartrates, and, perhaps most commonly, alcoholic drinks. The urine is scanty or suppressed in acute nephritis, hydræmic nephritis, in obstruction of the ureter unless the other kidney is equal to the task of secreting twice its normal amount, in all febrile processes, in cardiac failure, and after repeated vomiting, or profuse diarrhœa.

Specific Gravity. This varies directly as the amount of solids in the urine, inversely as the quantity of water—that is, of the urine itself. A hydrometer, called a *urinometer*, is used to determine it. If the quantity of urine is too small to float the urinometer, it may be diluted with one, two, or three volumes of water, as may be required, and the specific gravity will be obtained by multiplying the last two figures by the number which represents the dilution. The density varies with the temperature. For accurate record all observations should be made at 60° F., or corrections should be made by adding one degree of density for every 8° F. above 60° F. The urine in health usually has a specific gravity of 1,015 to 1,025. It is diminished by most of the causes of polyuria, so as to be 1,010, 1,006, 1,004, or less. It is increased by all the causes of scanty urine. In diabetes mellitus the specific gravity may be increased to 1,030, 1,040, or 1,050, although the quantity of urine is many times more than the normal; the unnatural excretion of large quantities of sugar accounts for this exceptional condition. Albumin occurs in urine of both low and high specific gravity.

The relative amounts of the various constituents of blood and urine and the average twenty-four hourly output are shown in the table on p. 422. A description of certain of them is given below.

Urea. This constitutes about one-half the total solids of the urine, and is the chief form in which the nitrogen of the body is excreted.

Quantitative Estimation. A convenient method of estimating the urea is to

decompose it by the addition of *sodium hypobromite* (or *hypochlorite*) into carbonic acid, water, and nitrogen—

A measured quantity of urine (5 c.c.) is mixed with a quantity of the hypobromite solution in a bottle, and the nitrogen is collected in a graduated tube and measured. The bottle and tube are surrounded with water so as to keep the temperature constant. The hypobromite solution rather readily undergoes decomposition on keeping. The nitrogen is measured, and from that the amount of urea can be calculated from the fact that 1 gm. corresponds to 370 c.c. of gas measured over water at 15° and 760 mm.

The determination of the output of urea in the twenty-four hours is a rough measure of the amount of protein metabolism. A more accurate way of measuring the latter is to estimate the total nitrogen of the urine by Kjeldahl's method. Allowance must also be made for the loss of nitrogen in the fæces, sweat, etc. Under normal conditions the nitrogenous content of the body remains constant, so that the excretion of nitrogen exactly balances the amount contained in the protein of the food, and varies from day to day as the amount of protein in the food varies. In disease the nitrogenous content of the body may vary, and this will produce its effect on the nitrogen excreted in the urine. For instance, in fever there is a destruction of body proteins, whereas in Bright's disease there may be a retention of nitrogenous products. This will show itself by an increase or decrease in the urinary nitrogen relatively to the protein consumed in the food. Such changes can only be measured if the patient eats an absolutely constant diet over a period of days.

Chlorides. These are lessened in all acute febrile processes, and especially in pneumonia, where they may be entirely absent.

Sulphates. These result from protein catabolism. The ethereal sulphates are partly the result of putrefaction in the intestines, and are largely increased in disorders of the intestines (obstruction, peritonitis, constipation) leading to such changes. The sulphates may be absent in lysol or carbolic acid poisoning and intravenous sodium sulphate (5 ounces of a 10 per cent. solution made with crystalline sodium sulphate) should be given immediately.

Phosphates. The chief function of the phosphates in the urine is to play the part of what are known as "buffers." This means that a large amount of acid or alkali may be passed from the blood into the urine without altering very greatly the acidity (hydrogen ion concentration) of the latter. In this connection the two most important compounds are the monosodium dihydrogen phosphate (NaH_2PO_4) and the disodium monohydrogen phosphate (Na_2HPO_4). The result of excreting acid is to form more of the former compound, and of excreting alkali more of the latter. A rich protein diet increases the acidity of the urine. It may be made more alkaline from the ingestion of much vegetable matter or other food containing citrates, tartrates, or malates of potassium and sodium. These are converted into alkaline carbonates in the intestines, and absorbed as such into the blood, and hence diminish the acidity of the urine; the pH is 7 or greater. In these circumstances the less soluble phosphates preponderate, and those of the earthy salts, calcium and magnesium, may be precipitated in the urinary tract, a condition known as *phosphaturia* (see Treatment of Calculus, p. 550); the turbid, white deposit is soluble on adding a little acetic acid. But more commonly it is found that on heating a feebly acid or neutral urine a white deposit of phosphates appears, which closely resembles albumin, but is at once distinguished from it by being dissolved by a drop of acetic acid. The urine may become alkaline from the presence of ammonia, which is formed as the result of bacterial decomposition of urea, either within the bladder (cystitis) or after standing in a vessel exposed to the air. In this case ammonium magnesium phosphate is precipitated ($\text{MgNH}_4\text{PO}_4 + 6\text{H}_2\text{O}$). It forms triangular prisms, with bevelled ends.

Reaction of the Urine. The reaction of the urine (hydrogen ion concentration) is usually on the acid side of neutrality. Hasselbalch has shown that the p_H may vary from -5.0 on a meat diet or during starvation to -8.0 when a diet containing vegetables and free alkali is eaten, depending on the relative amounts of Na_2HPO_4 and NaH_2PO_4 present in the urine.

The kidney may be regarded as an organ which secretes a large amount of acid in the twenty-four hours, forming from the neutral blood a liquid, viz. urine, with an acid reaction, and this is another way of looking at the acidity of the urine. The amount of the acid excreted is determined by titrating the urine with decinormal soda back to the neutral point, *i.e.* the reaction of the blood, neutral red being used as an indicator. In health there are wide variations; but the average value for twenty-four hours on a rather high protein diet is about 600 c.c. decinormal acid (Folin).

The term *amphoteric reaction* is used when the urine turns blue litmus red, and red litmus blue; this is the safe zone where there is no precipitation in urinary lithiasis; if both these changes of colour occur readily the p_H is 6.4. If the red paper only turns a very faint blue, the p_H is 6, and if it does not turn blue at all the reaction is below 6, which favours uric acid precipitation. If the red paper turns blue easily and the red paper shows no change the p_H is 7 or above, which is the zone of phosphate precipitation (2). Other indicators may be used, such as methyl red in spirit which is added a drop at a time—a pink colour means a p_H under 6, a yellow colour means a p_H over 7; series of tubes are sold showing the grading of colour of indicators with change of p_H . (*See also* p. 538.)

When it is desired to render a patient's urine alkaline, the best means of doing so is to administer repeated drachm doses of the potassium or sodium salt of citric, tartaric, or malic acids, which act as below explained; but sodium bicarbonate is the most effective. The acidity of the urine is increased in fevers and diabetes. It may be artificially increased by administering acid sodium phosphate (30 grains) by the mouth three or four times a day, or calcium chloride or ammonium chloride in 15 grain doses, four or five times a day.

Calcium Oxalate. The quantity of calcium oxalate secreted daily is only about 15 to 20 milligrams a day, but it is sometimes seen as a deposit in the urine, or it forms calculi in the kidney. Under the microscope will be found the minute octahedra of calcium oxalate, looking often like square envelopes. In different positions they may seem to have a rhombic or hexagonal outline, and if the edges are not developed they may form square prisms, with pyramidal ends. A not uncommon variety is that of the "dumb-bell," which is really a disc, with a central depression on either face, lying on its side, and seen edgewise. Such formations no doubt result from slow precipitation in the presence of colloid matter.

Oxalic acid may result from the catabolism of proteins and the purin containing nucleo-proteins, and possibly even from carbohydrates and fats by oxidation. There are only four foods which contain enormous quantities of oxalic acid (4); these are cocoa 450 milligramme per cent., sorrel 360, spinach 320, and rhubarb 240. So far as published figures go, the next in order are dried figs 100, chocolate 90, and potatoes 40; this is a very different list to that ordinarily published. Oxaluria is frequently present without symptoms; when these occur they are pain and sometimes hæmaturia, rather similar to renal calculus, and occasionally severe attacks have simulated acute intestinal obstruction. A non-purin low protein diet is indicated, with avoidance of oxalate-containing foods.

Uric Acids and Urates. Although the daily excretion of urates is quite small, the free acid and its salts are not infrequently deposited from the urine. (*See also* Reaction of Urine, Treatment of Renal Calculus and Gout.)

Uric acid is precipitated in acid urine of p_H 5.7 and below. The deposit is scanty and looks like Cayenne pepper. Under the microscope the crystals show

themselves as yellow fusiform or lozenge-shaped crystals, with sharp ends and rounded sides ; or as shorter and thicker crystals, with blunt extremities and more barrel-shaped ; but generally in some modification of the diamond shape. They are frequently grouped together in radiating clumps or star-like masses.

Urates are, as a rule, precipitated, in an amorphous form, as a thick pink or red sediment (*brick-dust* or *lateritious*). The causes of their deposition are (1) the cooling of the urine, because they are abundantly soluble at the body temperature, and very much less so at 50° or 60° F. ; and (2) concentration of the urine. A gentle heat will at once dissolve the deposit ; and if the urine is being tested for albumin, the urates dissolve, and leave the fluid clear before the albumin begins to appear. (3) Acidity of the urine also favours the deposition of the urates ; and in some urines the addition of acetic acid prior to testing for albumin will cause a precipitate of urates, which will redissolve on heating.

Urinary Pigments. The urine varies in colour both in health and disease. In health it is sufficient to distinguish between pale urines of low specific gravity, normal-coloured urines, and high-coloured urines of high S.G. ; while in disease we may observe, in addition, different shades of red, reddish-brown, and brownish-black from the admixture of blood, urobilin, or bile-pigment, and an opaque white colour in chyluria.

There are several pigments in the urine. Probably its colour is chiefly due, as shown by A. E. Garrod, to an iron-free pigment named *urochrome*. This pigment obscures the violet end of the spectrum, but gives no absorption bands. *Urobilin* exists in the normal urine in only small quantities, 1 to 2 grains in twenty-four hours ; it gives a definite spectrum, with an absorption band at Fraunhofer's line F—that is, between the green and the blue. The chemical test of its presence is to render the urine strongly alkaline with ammonia solution, filter, and add a few drops of a 10 per cent. aqueous or alcoholic solution of zinc chloride : a green fluorescence occurs if urobilin is present. Urobilin is probably absorbed from the intestine, where it is originally derived from bilirubin. Urobilin is in excess in fevers, in some diseases of the liver, in cardiac failure, in excessive hæmolysis (*e.g.* in pernicious anæmia and in acholuric jaundice), and during absorption of extravasated blood. It is diminished when the formation of bile is checked (phosphorus poisoning, acute yellow atrophy) or the bile duct is occluded. *Hæmatoporphyrin* is derived from hæmoglobin ; it occurs in minute quantities both in health and in disease, and more abundantly in the urine of rheumatic fever and some other disorders. It may not cause any appreciable difference in tint, and though it exists in quantity in some dark red urines passed after the administration of sulphonal, the dark colour is mainly due to other pigments. There is a rare in-born error of metabolism, in which hæmatoporphyrin is passed in the urine giving it a ruby-red colour. Porphyrins are present in the fæces and the skin is very sensitive to light, which causes a bullous eruption of *hydraea aestivale* (2). *Uroerythrin* is another pigment, which gives the colour to pink urates. Uric acid deposits are coloured by urochrome, and also sometimes by uroerythrin (Garrod).

The urine may also contain *chromogens*—that is, bodies which do not at the time colour the urine, but develop a colour either on standing, or on the addition of oxidising agents. The following are known : (1) the chromogen of urobilin, urobilinogen, shown to exist in febrile urine by the addition of nitric acid ; (2) a chromogen found sometimes in the urine of anæmia, which, though quite pale when passed, may yield a deep red colour on the addition of nitric acid ; (3) the chromogen of *melanin*, a black pigment which is developed on exposure, or on the addition of nitric acid, in the urine of patients suffering from melanotic sarcoma, although it is clear when passed ; (4) indican, or potassium indoxylsulphate, the chromogen of indigo-blue. This is the result of the absorption from the intestinal canal of indol, which results from the bacterial decomposition

of proteids. It exists in normal urine to a very small extent, but is greatly increased in all conditions leading to retention of intestinal contents. Its presence is detected by the addition of an equal quantity of hydrochloric acid, and then a few drops of a saturated solution of calcium hypochlorite. Indigo is thus formed, and colours the mixture blue or violet. It can be separated by shaking with chloroform, which then forms a blue layer at the bottom of the test-tube. Sometimes the addition of nitric acid alone develops a blue, violet, or blackish colour, due to the separation of indigo.

In *alkaptonuria* the urine is of a natural colour when passed, but darkens on exposure, is darkened rapidly by alkalis when warmed, is turned deep blue by a dilute solution of ferric chloride, and is found to contain homogentisic acid, and sometimes uroleucic acid. The condition is rare, but in many of the cases it is congenital, and occurs in two or more members of the same family, and the children of parents who are blood-relatives. It causes no symptoms (*see* Ochrosis).

Several *medicinal and other chemical substances* colour the urine, or give colour-reactions with tests employed for other purposes. Rhubarb, which contains chrysophanic acid, makes the urine a deeper yellow; and santonin the same. The addition of an alkali will turn these urines red. Logwood gives a reddish tinge to the urine. Carbolic acid, taken internally, or absorbed from carbolic dressings, often causes the urine to become dark brown or greenish-black on exposure, though clear when passed, from the presence of pyrocatechin and hydroquinone. Creosote may have the same effect. Methylene blue, taken internally, renders the urine blue, or, if in small quantity, green. Eosin, used to colour toys or sweets, has caused a bright red urine in children. If potassium iodide or potassium bromide is being taken, nitric acid may darken the urine from the liberation of free iodine or bromine. Free iodine or bromine can be separated by shaking with chloroform.

ALBUMINURIA

The term *albuminuria* is commonly used to denote the presence both of serum albumin and globulin in the urine. The serum globulin is often in excess in the urine of lardaceous disease, and may be detected by pouring the urine into a large bulk of distilled water, when the globulin is precipitated, or by saturating the neutralised urine with magnesium sulphate. On the other hand, in chronic parenchymatous nephritis the globulin in the urine is much diminished relatively to the albumin, the ratio being 1 to 6. In cases of functional albuminuria this ratio is usually 1 to 2.

Albuminuria may be detected in various ways.

Heat. If clear acid urine containing albumin be heated in a test-tube, it will become opaque from the coagulation of this substance. According to its quantity there will be a mere opalescence, a decided turbidity, or a thick creamy deposit. The best way of applying the test is to fill a test-tube to one-half or two-thirds of its length, then add a few drops of dilute acetic acid, and, holding it by its lower end, warm the upper part of the urine. The heat is thus confined to that portion of the urine, and whatever slight change takes place in the clearness can be recognised by comparison with the cool urine below.

Some precautions are necessary. First, heat may precipitate substances which are not albumin, *i.e.* phosphates, which, however, are at once dissolved by a drop of nitric or acetic acid. Secondly, albumin, though present, may fail to be coagulated by heat. This occurs when the urine is not sufficiently acid, and the serum-albumin has been converted into alkali-albumin, which is not precipitated by heat; the fallacy can be guarded against by the addition of acetic acid to the urine after boiling, so as to render it acid. In any case the experiment must be performed upon a clear urine: if turbid from urates, a gentle

heat clears it ; if from phosphates, a drop or two of acetic acid should be added ; if from any other deposit, the urine should be filtered.

Nitric Acid. The test is best applied by placing a little nitric acid in the bottom of a test-tube and very gently pouring the suspected urine down the side of the tube, so that it flows on to the surface of the acid without mixing with it. At the line of junction a layer of albumin forms, of white colour if abundant, or a thin grey disc when the quantity is very small. In the former case also it forms at once ; in the latter it may take several seconds, or two or three minutes, or even half an hour.

There are but few fallacies connected with this test. First, in urine containing an excess of urates, these are sometimes precipitated as a cloud or haze some distance above the nitric acid, instead of lying immediately upon it ; the application of a gentle heat will at once dissolve them. Secondly, nucleo-protein (mucin) is precipitated as a haze in the same position. Thirdly, the urine of persons who are taking copaiba internally contains a resinous acid, copaivic acid, in combination with bases. If nitric acid be added to this the resinous body is thrown down, generally as a cloud, evenly diffused through the urine. This precipitate is also dissolved by heat. Fourthly, the addition of nitric acid may give rise after some time, when the mixture has become cold, to a crystalline deposit of nitrate of urea ; but this has no resemblance to albumin, consisting, as it does, of lamellar crystals, radiating in various directions. Nitric acid also precipitates the albumoses, which are redissolved by heat.

Picric Acid. A test-tube should be more than half filled with urine, and a saturated solution of picric acid, which has a low specific gravity, should be poured on to it so that the liquids may mix as little as possible ; at the line of junction a delicate white line, or a thicker white cloud, at once forms, which, if albumin, is not dissolved by heat. Besides albumin, picric acid also precipitates urates, alkaloids, and albumoses. These are said to disappear at once on warming the urine. Quinine is the only alkaloid that is likely to be taken in sufficient quantity to be precipitated by picric acid. Nucleo-protein is also precipitated by picric acid and is not dissolved by heat. If picric acid gives no precipitate albumin is certainly absent.

Salicyl-sulphonic Acid. A saturated solution of this acid is a delicate test for albumin : added to clear urine in a test-tube, it throws down an opalescent cloud of albumin. It is useful for confirming the results obtained by the heat test. Albumoses are also precipitated.

The following are *quantitative tests* for albumin :

Esbach's Test. This method is simple but uncertain and inaccurate. A test solution is prepared, consisting of one part of picric acid and two parts of air-dried citric acid in 100 parts of water. A graduated tube from 6 to 8 inches long and $\frac{1}{2}$ inch in diameter is filled up to a certain level ($2\frac{1}{4}$ inches) with urine, and then for a certain distance ($1\frac{1}{2}$ inches) with the picric solution. The precipitated albumin is allowed to settle for twenty-four hours, and the marks on the tube show the amount of albumin contained in 1,000 parts of the urine, *i.e.* grammes per litre.

Kerridge's Test. This is the best clinical method and should come into general use. 1 c.c. of urine (or cerebrospinal fluid) is shaken in a small standard test-tube with 0.1 c.c. of a carbon suspension and then with 0.1 c.c. of trichloro-acetic acid ; the colour is compared with standard tubes (6).

The Causes of Albuminuria. In considering the reason why albumin appears in the urine in Bright's disease, we must remember that the occurrence of albuminuria is not limited to cases of nephritis, but accompanies a variety of other disorders. The different conditions in which albuminuria has been observed may be enumerated as follows :

I. Arising in the kidney—

1. Bright's disease in its varieties, as detailed later ; acute fevers.

2. Pyelonephritis, including calculous pyelonephritis; and metastatic nephritis.
 3. Tuberculous kidney.
 4. Lardaceous disease.
 5. Venous obstruction in diseases of the heart and lungs, and local disturbances of the circulation.
 6. Cystic disease.
 7. New growths, including leukæmia; and parasites.
 8. Hydronephrosis and temporary obstruction of the ureters; pregnancy.
 9. Functional albuminuria.
 10. The presence of foreign proteins in the blood and Bence Jones albumosuria.
- II. Arising in the urinary passages below the kidney—
1. Disease of the pelvis of the kidney and the ureters.
 2. Cystitis.

In this last group, the albuminuria is always slight, since it is merely either a part of the pus that exudes directly from an ulcerated stratified mucous membrane, or blood that may be the result from rupture of vessels as in the case of calculus.

Other Proteins of the Urine. *Nucleo-protein, Euglobulin.* If a few drops of acetic acid be added to the cold urine, especially if diluted, a precipitate may form, which was once thought to be mucin, and more recently a nucleo-protein derived from the renal cells. Such precipitates have been considered by Mörner to be compounds of serum-albumin with chondroitin-sulphuric acid, with nucleic acid, and in cases of jaundice with taurocholic acid. On the other hand, they have been thought to be a mixture of euglobulin and fibrinogen (Oswald). The practical importance of this substance, euglobulin, or whatever else it turns out to be, is that it may be the substance that causes functional albuminuria in young persons (*see p. 551*). It is generally agreed that its presence in quantity definitely excludes the case from the category of true nephritis, so that the prognosis is good.

Specific *proteoses* occur in the urine in asthma and other allergic conditions (*q.v.*), in tuberculosis, influenza, and probably in most if not all infective febrile conditions. Proof has been obtained that the patients are sensitised to their own proteose by means of skin reactions, and in influenza and in one case of purpura tested the proteose was associated with a hæmolysin. To test for proteose, urine acidified with a few drops of 25 per cent. sulphuric acid is shaken with a quarter of its volume of ether, when the ether layer becomes opaque and viscous (4).

Bence Jones *protein*, which occurs in multiple myeloma of the bone-marrow (*myelopathic albumosuria*), and occasionally in myelogenous leukæmia, is coagulated by a lower temperature than albumin, that is 58° C. (137° F.), as compared with 75° C. (167° F.), and the coagulum is re-dissolved as the temperature is raised to boiling. It is precipitated by a saturated solution of ammonium sulphate. Strong hydrochloric and nitric acid throws down an abundant precipitate, which is only dissolved in very great excess of acid, but is soluble on boiling. In smaller quantity, an amount of the protein equal to 0.5 per 1,000 will give a white ring at the junction of the fluids, when the urine is floated on the acid (Bradshaw's test).

Peptones rarely, if ever, occur in the urine. They give the biuret reaction—a pink or rose colour when the urine is floated in a test-tube over a small quantity of Fehling's solution—but they are not precipitated by nitric acid, nor by saturation of the fluid with ammonium sulphate, which precipitates the other proteins. This and other salts may be used for the separation of the proteins, since ammonium sulphate precipitates all proteins, except peptones, sodium magnesium sulphate precipitates serum-albumin, and magnesium sulphate throws down serum-globulin.

HÆMATURIA

Blood may be present in the urine in obviously large amounts, forming clots, or in sufficient quantity to give the urine a bright red colour. When there is less present the urine often has a dirty-brown colour and turbid "smoky" appearance from the presence of methæmoglobin or hæmatin; generally with this there is a granular reddish-brown sediment. It must, of course, not be forgotten that the urine may be coloured red by hæmoglobin without the presence of actual blood, and by some other red pigments (*see pp. 444, 510*). The presence of blood is determined in several ways.

The Microscope. By this we can recognise red blood cells in cases where there is no suspicion, from the colour of the urine, that blood is present; if the urine is distinctly red, or brown and turbid, the discs will be there in abundance. From suspension in the urine they may have lost their bi-concave form, and are often shrivelled, and have crenated edges, or may present protrusions of their substance. They remain visible for the longest time in acid and dense urines, but may be quickly dissolved in ammoniacal urine, or in urine of low specific gravity.

The Spectroscope. The spectrum of urine containing oxyhæmoglobin shows two absorption bands in the yellow and green portions between Fraunhofer's lines D and E, the narrower, darker, better-defined band being nearer to D. Methæmoglobin gives three absorption bands, two in very nearly the same position as those of oxyhæmoglobin, and a third about half-way between C and D. Acid hæmatin shows a fourth band between E and F.

The Guaiacum Test. To the urine, in a test-tube, are added a few drops of tincture of guaiacum, and then about $\frac{1}{2}$ drachm of ozonic ether or ozonic alcohol, which contain hydrogen peroxide. Quickly or slowly, according to the quantity of blood, a blue colour forms at the junction of the fluids, and diffuses itself through the ether which floats on the surface; its appearance may be hastened by gently shaking the mixture. The test is not absolutely trustworthy. The urine of patients taking potassium iodide will give a blue colour, but it appears only slowly unless the iodide is in very large amount.

Causes of Profuse Hæmaturia. For convenience these may be classified as (1) Surgical, though with medical bearings—renal calculus, tuberculosis, neoplasm, aberrant renal artery, enlarged prostate, papilloma of bladder, (2) Medical (roughly in order of frequency)—acute nephritis, tubal nephritis, and secondary and primary contracted kidney, hyperpiesia; heart disease, *e.g.* infective endocarditis, and mitral stenosis with infarction or congestion; urinary tract infection; purpura, anæmia, polycythæmia; irritation by drugs, such as hexamine, carbolic applications, and rhubarb; oxaluria and bilharziasis.

The recognition of the true cause of hæmaturia has frequently failed in the past, and so the term *Essential Hæmaturia* or *nephrostaxis* has often been used, and even now, occasionally, no cause can be assigned to a case; but it is wiser and simpler to plead ignorance than to perpetuate an unexplained pathology. No doubt some cases are due to minute nævi in the renal pelvis, and a number of cases of purpura of the urinary tract have been described.

Diagnosis. Cystoscopy, etc. should be used to determine from what part of the urinary tract the blood is coming; however, it is useful to remember that in urethral hæmorrhage the blood is discharged separately and is not mixed with the urine.

CASTS

These are solid bodies, which are detected by the microscope in the urine, and if sufficiently numerous form a sediment visible to the naked eye. Where they are too few to be easily detected, they may be found after centrifugalising the urine. They are cylindrical in shape and from 0.01 to 0.05 mm. in breadth; but they vary still more in their length, which may reach 1 or even 2 mm., so as to

stretch right across the field of the microscope, but is more often from five to ten times the breadth. Their connection with the kidney is proved by finding them after death, *in situ*, usually in the junctional tubules. They are probably formed in the loop of Henle, since the lumen of the tube is much narrower here than elsewhere, so that the material becomes squeezed as it passes through. The following varieties are distinguished :—

Hyaline Casts. These are transparent colourless cylinders, with refractive properties so like those of the fluid in which they lie, that they are discovered with great difficulty, unless they are stained by the addition of carmine or iodine, or one of the aniline dyes, such as gentian-violet. They are homogeneous, soft, and flexible, straight or curved, and varying in length. Occasionally they have other deposits adherent to, or embedded in, them, such as red blood corpuscles, leucocytes, epithelial cells, granular masses, fatty granular globules, crystals of urates or oxalates, or particles of hæmatoidin.

Some of the varieties of casts described below probably have the same hyaline material as a basis, which is then completely covered by, or mixed up with, the other elements.

Hyaline casts are often spoken of as “fibrinous,” but it appears that they are not pure fibrin. Most probably they are formed from an albuminous coagulate, which has transuded through damaged epithelium from the blood. More rarely they are formed from tubular epithelium, which has undergone hyaline degeneration.

They occur in the different forms of nephritis, and in the congestion produced by heart disease; they are nearly always associated with the albuminuria of renal origin, but may precede for a few hours or days the appearance of the albumin, and may continue for a time after its disappearance.

Epithelial Casts. These consist of cells of the renal epithelium held together by, or embedded in, the coagulable material which makes up the hyaline casts. The epithelial cells may be more or less distinct; they may come from the convoluted tubule or the loop of Henle.

Granular Casts. These are not so transparent as hyaline casts, being sometimes like ground glass, sometimes darker and much more opaque. They are formed by the degeneration of epithelial cells, and in many cases it is possible to see the outlines of the epithelial cells in the cast.

Fatty Casts. These are either hyaline casts in which globules and granules of fat are embedded, probably from the disintegration of epithelium in a state of fatty degeneration; or they actually consist of such fatty epithelial cells themselves. *Lipoid* casts show double refraction, when examined with the polarising microscope.

Blood Casts. These result from the coagulation of blood which has been effused into the renal tubules; they are easily recognised by their colour, and by the size and close aggregation of the blood corpuscles composing them. Their presence in a case of hæmaturia proves that the blood comes from the kidney itself.

Waxy Casts. These are large and highly refractive casts, which are sometimes found in cases of lardaceous disease, but also in other chronic forms of Bright's disease. They are brittle, and break irregularly, which gives them rather the appearance of wax. They often do not give the reactions of lardaceous material, and their nature is doubtful, but it is possible that they are a later stage of the granular cast.

Though the character of the casts found in the urine must be determined to some extent by the condition of the kidney, conclusions on this last point must not be too hastily drawn from them. Frequently two or more forms are found in the same urine, and we must be guided by the predominance of one or the other. Hyaline and granular casts are found in all forms of nephritis, acute or chronic. Blood casts and epithelial casts are most common in acute cases;

fatty casts are most frequent in cases of chronic nephritis, in which fatty degeneration has supervened.

Leucocyte Casts. This is the name given to casts in which pus cells are embedded.

Cylindroids. These are large hyaline bodies with tapering or branching ends, a wavy outline, and longitudinal striation : they are probably threads of mucus, the undissolved residue of nucleo-proteid, and not really casts. They have no significance.

THE ESTIMATION OF THE RENAL FUNCTIONS

Water Output Test. To test the ability of the kidneys to excrete water, 1,200 c.c. water are taken in the early morning without breakfast. At least 900 c.c. urine should be excreted during the following five hours, and the specific gravity should be 1,003.

The Concentration or Specific Gravity Test. No fluids are allowed for twelve or sixteen hours, and a high-protein supper with salt is given at 6 p.m. Three specimens are collected, on waking, and at hourly intervals. The maximum specific gravity should be at least 1,026 ; otherwise the concentrating power is deficient.

Estimation of Urea in Blood. The simplest and shortest method is Yvon's. Ten cubic centimetres of blood from a vein are mixed with 5 c.c. trichloroacetic acid to precipitate the proteins and made up to 25 c.c. in a small measuring flask. The mixture is filtered into a measuring glass and the volume of the filtrate noted. This is made alkaline with caustic soda, phenolphthalein being used as an indicator. The measuring apparatus consists of a small funnel connected below by a stopcock with a short burette. On the lower end of the burette a rubber bag is fixed containing some glass beads. The bag is squeezed, and the apparatus is filled with the alkaline filtrate, which is carefully washed in, all the air being expelled from the bag and burette, and the stopcock is then closed. Some sodium hypobromite is poured into the funnel, and is allowed to enter the burette. The contents of the latter are mixed by inverting it several times. The nitrogen liberated is collected at the top of the burette, and is measured by transferring the burette to a cylinder of water and removing the bag. The calculation follows from the fact that 1 gramme urea corresponds to 370 c.c. of gas measured over water at 15° C. and 760 mm.

Normally the blood contains 30 milligrammes per cent. Figures of ten times this amount are found in uræmic coma. Cerebro-spinal fluid may also be used. In this case it is unnecessary to remove the proteins with trichloroacetic acid.

Urea Concentration Test. The patient abstains from fluid for fifteen hours ; on waking in the morning, he empties his bladder, and immediately drinks 100 c.c. of a solution containing 15 grammes urea flavoured with tincture of orange. One hour later he passes urine, and again after a second and third hour. The percentage of urea is determined in the two specimens. If the percentage is above 2, the excretory power is satisfactory. It has been found that this test is only accurate if the volume of urine passed is about 100 c.c. (9). So the writer advocates returning to the principle of McCaskey's original method as follows :—

The Rate of Urea Output Test. The procedure of the urea concentration is followed ; but there is no necessity to restrict the fluid unduly beforehand. From the hourly volumes and the urea percentages the maximum amount of urea passed during one of the three hours is calculated. The minimum amount of urea which healthy kidneys excrete varies a little with the volume of urine as below :—

Hourly volume, c.c.	50	60	70	80	100	120	150	200	250
Urea output (gms. per hr.)	1.81	1.92	2.0	2.05	2.08	2.09	2.10	2.10	2.2

If the maximum hourly urea output of a patient falls below the minimum figures in the second line of the above table, the excretory power of the kidneys is to be regarded as deficient.

Blood Urea Clearance Test. As this test was originally described, the patient at 6 a.m., without breakfast, drinks slowly 1000 c.c. of water (35 ozs.) containing 30 grammes of urea. If the urea concentration in the blood is already high, *i.e.* 60 milligrammes per cent., no urea need be taken. At 7 a.m. and every hour afterwards until 11 a.m. the patient drinks slowly two glasses of water (about 16 ozs.). The amount of urea passed in the urine during each hour between 9 a.m. and 12 noon is determined and samples of blood for blood urea estimations are taken at 9.30, 10.30 and 11.30 a.m. Then the ratio of the amount of urea passed per unit time to the concentration of urea in the blood is a constant—in other words, as the urea in the blood rises, so the amount passed in the urine increases. To avoid taking such a large quantity of urea the writer gives a dose of 15 grammes at 8 a.m.

The amount of urea (u) passed per minute in a volume of urine (v) may be looked upon as coming from a volume of blood (V), which contained an amount (U) of urea before the kidney had completely cleared it out, so that the $UV = uv$.

Therefore $V = \frac{uv}{U}$, a fraction which is the same as the ratio above. Hence this constant represents a hypothetical volume of blood which in the space of a minute has been cleared of its urea—hypothetical because no portion of blood is ever cleared of its urea completely. The constant is called the *maximum clearance*, because during the test the kidney is working up to its maximum capacity to get rid of water and urea. It is a measure of the amount of functional renal tissue present in the body, and it provides the best test of renal function at present available. In an adult the maximum clearance varies within a range of 60 to 94 c.c. per minute, average 75 c.c. In the case of children and of individuals varying considerably from the normal in size (*e.g.* wt. 10 stone and ht.

5 ft. 7 in.), the value obtained must be multiplied by $\frac{1.73}{\text{the body surface in sq. metres}}$ before it is comparable to the normal figures just mentioned (*see also* p. 460). The body surface is calculated from the height and weight as explained on p. 460 (10). This test may be looked on as an extension of the last test since blood urea comes in as a factor additional to concentration and volume; in fact, rate of urea output is only satisfactory, because, when the blood urea is normal beforehand, it usually rises to a constant level after giving 15 grammes urea.

Example: the figures obtained from an adult male for each of the two last hours of the test were as follows: Urine vol., 483, 466 c.c.; urea percentage, 0.47, 0.48; blood (milligrammes per cent.), 0.48 and 0.45. The maximum clearances per minute were $\frac{470}{48} \times 8.05$, $\frac{480}{45} \times 7.75$, and multiplying out 79, 83. Mean = 81—a normal figure.

It is claimed that reliable results are obtained even when the volume of urine is as low as 120 c.c. per hour, but below this figure the clearance fraction, which is no longer now a maximum, is not constant. This is a disadvantage, because the diuresis of hydræmic nephritis will often not even reach this figure. But a fair approximation may be arrived at by using \sqrt{v} , in the case of children

$\sqrt{\frac{v \times 1.73}{\text{Body Surface}}}$, instead of v in the above equation. This is the *standard clearance* and the normal range is 41–67 c.c.; and the mean 54 c.c. (11). This modified formula may be used when the blood and urine are analysed over hourly periods without giving either urea or water; but the maximum clearance test is probably best. A similar test with creatinine has been described (12).

Estimation of Diastase in the Urine. This test has been described on

(b) *Theories of Renal Œdema.* There is normally a balance between the blood in the capillaries and the tissue fluids, which prevents any excessive exudation of fluid from the capillaries. The osmotic pressure of the blood proteins plays a part in this balance. The loss of the smaller protein molecules means that the osmotic pressure in the plasma due to the proteins is greatly diminished and the equilibrium between the blood and tissue fluids is upset, and so fluid and salts escape into the tissues, which become œdematous, the protein content of the dropsical fluid being very low. This is Epstein's theory of œdema. Now it is an undoubted fact that the osmotic pressure of the plasma is lowered in renal œdema, and the serum albumin with its smaller molecules is also diminished relatively to the serum globulin; but there are, in the writer's opinion, three objections to these changes being regarded as the cause of renal œdema: (a) a lowered osmotic pressure would mean a greater filtration pressure through the glomeruli, so that the agency that drove the fluid out into the tissues would also increase the flow of urine; a balance would result; (b) the transfusion of 500 c.c. blood in one case did not cause a diuresis; it only increased the albuminuria (39); (c) in one case of the writer's the œdema rapidly subsided, while the protein in the serum still remained at the same low value. Two other theories have been advanced to account for renal œdema: (1) It has been suggested that the systemic capillaries are injured through some intoxication and so become more permeable to the fluid parts of the blood; but it is difficult to see why a toxin should get into the blood in just those cases of renal disease, where the excretion of protein catabolites is not greatly interfered with, while many cases with very seriously impaired renal efficiency, *i.e.* secondary contracted kidney, do not suffer from œdema at all. (2) It has been suggested that the œdema follows because the kidneys cannot excrete chloride, and if salt is retained water must also be retained so as to preserve the isotonicity of the body fluids, and œdema results. But it has been shown that excess of water by itself leads to œdema (20). However, if salt is added as well, the tendency to œdema is still further increased. The latter was shown by a case of the writer's, where, in spite of a low blood chloride, the administration of salt and water for a special therapeutic purpose not only caused an increase of body weight, from œdema, but also diminished the flow of urine, which remained low for some time. In the writer's opinion, the simplest and most probable theory is that œdema is due to the blocking of the tubules, so that the glomerular filtrate from normal glomeruli trickles through so slowly that a larger proportion of chloride than normal is absorbed with its quota of water. Œdema follows when excess of water or of chloride and water are taken; if water is deficient owing to vomiting, for instance, there is retention of salt without œdema, the "dry retention" of French authors.

2. *Excretory Functions of the Kidneys.* (a) If there were complete obstruction of glomeruli or tubules, no fluid or salts could get through the kidney at all; there would be suppression of urine and accumulation of all the excretory products in the blood, in the same way as when both ureters are obstructed by calculus. If there was a partial obstruction, there would be a resistance to the excretion of water and salts, so that œdema might follow if the patient took plenty of fluid. If the tubal epithelium were not much interfered with, the excretion of urea might not be much below par, and unless too high a protein diet were eaten the urea would not accumulate in the blood. This is the case in one form of acute nephritis (nephritis mitis), where the tubules are obstructed. If there was glomerular destruction and this took place slowly, the resistance might be entirely compensated for by an increased pressure exerted on the glomeruli, and here again it is interesting to note that certain cases of war and civilian nephritis have recovered completely as far as the excretory powers of the kidney are concerned; but a permanent hyperpiesia has been the result (17).

(b) If the tubules were seriously affected alone the glomerular filtrate would be produced normally and there would be no high blood pressure. However, the con-

centration of urea would be seriously interfered with ; urea, sulphates, phosphates, etc., would be retained in the blood and the patient might die of uræmia without any circulatory symptoms, a condition which has also resulted from war nephritis. If the lower part of the tubules were alone affected the patient would merely pass an extremely dilute urine, but the excretory power of the kidney would be unaffected. It has been suggested that such a condition occurs in diabetes insipidus owing to the absence of posterior pituitary extract (7).

(c) If both glomeruli and tubules were simultaneously and gradually affected the condition described in secondary contracted kidney would be expected. A high blood pressure and hypertrophied heart would follow from the relative impermeability of the glomeruli. The functions of the tubules would be disturbed, so that urea, etc., would accumulate in the blood, and the destruction of the lower part of the tubules would prevent reabsorption of water, so that the patient would continually pass a very dilute urine of low specific gravity. This failure to reabsorb water would tend to prevent œdema. The same reasoning holds for those cases of nephritis repens in which large portions of the glomerulo-tubal systems are completely destroyed, leaving too small a number for the work of excretion.

ACUTE GLOMERULO-TUBAL (TOXIC) NEPHRITIS

Ætiology. This disease, commonly called *acute nephritis*, is a *diffuse* nephritis. The actual cause is at present unknown. There is, however, a general consensus of opinion that the disease is due to infection, though whether the kidneys are themselves the place where the organisms are growing or are solely affected by toxins which arise from micro-organisms in quite a different part of the body is an open question. In many of these cases the tonsils are septic, and it is quite common for an acute nephritis to be preceded by an acute tonsillitis, points which suggest that focal sepsis may be a primary cause ; in these cases the micro-organism implicated will be the streptococcus. Scarlet fever is a well-known cause of the condition, and in this case children are more often the subjects than adults. As a rule, the symptoms are first observed during convalescence, and the nephritis is presumably due to streptococcal invasion ; sometimes it commences before convalescence is established. However, of cases met with in a general hospital, acute tonsillitis is eight times as common as scarlet fever as the predisposing cause (17). Several other febrile diseases are sometimes the precursors of acute nephritis. They are coryza, acute rheumatism, measles, variola, cholera, varicella, typhus, enteric fever, pneumonia, relapsing fever, diphtheria, Henoch's purpura, tubercle, syphilis, and septic conditions, including empyema and wounds of the skin and scalp. The micro-organisms of some of these infections have been found in the urine, *e.g.* pneumococci and typhoid bacilli.

Exposure to cold and damp, particularly if the patient is under the influence of alcohol, is sometimes regarded as a predisposing cause. A very good example of the type of nephritis arising apparently spontaneously is the so-called "trench nephritis," which occurred among soldiers in the recent war ; it was not confined to soldiers in the trenches. Similar outbreaks have occurred in other campaigns, notably the American civil war. There is no essential difference between trench nephritis and the acute nephritis of civilian practice. Pregnancy is not infrequently the cause of nephritis, which may be of the most severe type, with uræmia and retinal changes.

Morbid Anatomy. In some cases the kidney may be of normal size and of normal appearance to the naked eye—a remarkable fact considering that the patient has died very often from virtual suppression of urine. This has been noted in cases of trench nephritis and scarlatinal nephritis when death has occurred rapidly. In other cases the kidney is more or less swollen ; it has a rounded form, is tense and elastic, the capsule strips readily, and

the surface is paler than normal. On section, the cortex is considerably swollen, and of greyish-red colour, while the pyramids are dark red from congestion. Here and there are bright red spots: some of them are congested glomeruli, others are small hæmorrhages. In yet other cases the kidneys are intensely congested, dark red or chocolate in colour, dripping with blood, and showing on section a still more extreme congestion of the pyramids.

Microscopically, when the inflammatory reaction is intense (nephritis acris), the glomerular tufts are swollen with a proliferative glomerulitis, and they contain many polymorphonuclear leucocytes. The cells of the tubal epithelium show a swollen granular protoplasm with disappearance of nuclei, cloudy swelling or albuminous degeneration, and they may contain hyaline droplets (hyaline droplet degeneration); dropsical, fatty and lipid degeneration may also be present, and there are hyaline and granular casts. The presence of doubly refracting lipid droplets constitutes lipid degeneration. The interstitial tissue is frequently œdematous, and there is periglomerular infiltration with polymorphonuclear leucocytes. When the inflammatory reaction is of low grade (nephritis mitis), the stroma of the glomeruli is œdematous. The endothelium of the capillaries of the tuft is swollen; there is cloudy swelling and lipid degeneration of the epithelium of Bowman's capsule, and very marked lipid degeneration of the epithelium of the renal tubules, while the nuclei of these cells are degenerated. Cellular and albuminous *débris* are frequently present in the capsular spaces, and the tubules contain hyaline and granular casts (24).

Pathology. There is interference with most of the renal functions during an attack of acute nephritis, but there is much variation from case to case. Owing to failure to excrete non-protein nitrogenous substances, there is a corresponding retention of them in the blood: this is shown by the rise in the urea content of the blood, which is considerable in some cases (180 milligrammes per cent.), though it is slight in others. The œdema may be due to the inability of the kidneys to excrete water and salts owing to deficient glomerular function. There may or may not be some deficiency in the excretion of diastase. A rise of blood pressure, both systolic and diastolic, accompanies the œdema in acute nephritis. Its effect is to increase the circulation of blood through the kidneys, and so help to keep up the flow of urine. It rapidly falls to normal when the œdema subsides and the volume of urine is increased.

Symptoms. The onset of symptoms is often insidious. Very often œdema is the first symptom noticed by the patient or his friends. The face looks puffy, the fluid collecting beneath the eyes in particular, when the patient rises in the morning. It may subside in the course of the day, but if the feet be examined at night there is œdema just below the ankles. There is, indeed, a small quantity of effusion into the subcutaneous tissue, which always seeks, by force of gravity, the most dependent part. During the daytime it reaches the feet; in the recumbent position of sleep it diffuses itself generally, but is most pronounced in the loose tissues of the eyelids. If the patient takes to his bed, it will leave both the face and the feet, and accumulate in the tissue over the sacrum, which has now become the most dependent part. The puffiness of the face is in marked contrast to the onset of œdema in cardiac failure, which gravitates downwards, becoming first of all visible in the legs. The duration of the œdema of acute nephritis varies greatly. In mild cases it may disappear in a day or two. On the other hand, it may continue, and the case eventually becomes one of large white kidney. Associated with the œdema there is diminution in the volume of urine and albuminuria. In the worst cases only a few ounces of urine of high specific gravity may be passed during the day, and it may become solid on boiling owing to the high concentration of albumin. In milder cases the volume of urine is greater, and it may be turbid and have a colour which is due to the presence of fresh or altered blood, and is dusky brown, deep brown, "porter-coloured," pink, or distinctly red, according to the quantity and condition of the

blood. In some cases hæmaturia may be present with no more albuminuria than would be accounted for by the blood (*Hæmorrhagic Nephritis*). The volume of urine is often not diminished in such cases.

Quite early the pulse becomes hard, and the blood pressure is raised, sometimes up to 180 mm. The rise is greater at night than in the morning. The heart sounds are modified. The first sound (systolic) increases in intensity, and the second sound (over the base of the heart) is also accentuated or "ringing" in character.

The patient may feel unwell; there may be some rise of temperature; there is anorexia and usually vomiting. Headache is complained of. There may be pain over the epigastrium associated with vomiting; but the writer considers that the pain described occasionally in the loins, means acute pyelonephritis (*q.v.*) and not acute nephritis. Anæmia may be present. Dyspnoea was a symptom that was very frequently noticed in trench nephritis. Edema of the lungs may have accounted for this symptom in some cases. In severe cases the heart dilates, and the impulse may be displaced outwards.

Uræmia in Acute Nephritis. In those cases where the suppression of urine is considerable uræmia may supervene. (1) This may be similar in its biochemical changes to the uræmia associated with secondary contracted kidney, which has been called the chronic or asthenic type of uræmia (*see p. 530*). (2) But there is another special type of uræmia called the *acute* or *sthenic* type, or sometimes *eclamptic* or *convulsive acute uræmia*, which is very characteristic of acute nephritis and which is not associated with a high urea or phosphate retention in the blood. In this type headache and vomiting become more severe, the pulse is slow, there may be Cheyne-Stokes respiration, and there are convulsions. Experience of trench nephritis during the war showed that these symptoms were due to cerebral œdema, since they could always be stopped by lumbar puncture, and the cerebro-spinal fluid was under considerable pressure. The convulsions are due to compression of the brain against the inside of the skull. There is a secondary rise of blood pressure. This type of uræmia has been regarded as due to chloride retention (18). The attacks have a very close resemblance to the ordinary attacks of epilepsy. There is often a short tonic stage, and then general clonic convulsions of all the muscles of the limbs, face, eyes, and trunk. Consciousness is lost, the face becomes livid, there is frothing at the mouth, the saliva may be tinged with blood, and the pupils are dilated. After some minutes the convulsions subside, and the patient may at once regain consciousness, and then improvement in the general condition may begin, for convulsions are by no means always an unfavourable sign. In other cases the patient lapses into a state of *coma*, from which he may again pass into convulsions; and these are repeated again and again with intervals of complete coma in which he may die. During the convulsion the respiration is hurried, and the pulse is small and quick; the temperature is variable, and it may reach 104°, or higher. This sequence of events may be repeated several times. Whilst the epileptiform attack is the classical expression of this type of uræmia, it is often absent and headache and vomiting may be present alone, and there may be temporary localised paralyses or hemiplegia and homonymous hemianopia or complete blindness (*uræmic amaurosis*). The latter may last from one to three days, and frequently passes off entirely. As the pupil reactions are unaffected, it is probably due to compression of the higher visual centres. Deafness may be also noticed, and there may be delirium or mania. These various manifestations often precede or follow the convulsions.

Ocular Changes. In the majority of cases of acute nephritis no changes in the retinae are observed, with the exception of small more or less circular hæmorrhages, which, however, are apt to occur in people failing in health. Out of 119 soldiers suffering from trench nephritis, Foster Moore observed definite eye changes in only five, coming on about two months after the beginning of the

illness. The blood pressure was higher (average 180 mm.) in these cases than in the remainder (average 143 mm.). The changes consisted of exudations at the back of the retina, leading often to its detachment. They were seen as pale, soft edged, oat-shaped swellings, arranged radially in some cases so as to form a star. Later on these swellings coalesced as the exudations became more extensive. Hæmorrhages were also present, and the edges of the optic disc were blurred by exudations (papillitis). In severe cases the swelling of the disc is so marked as to conceal completely the retinal vessels, and resemble the papilloedema of cerebral tumour. More often there is slight prominence, but diffused opacity spreads far on to the surrounding retina. These various changes are seen more often in chronic parenchymatous nephritis. They may be regarded as being due to toxic action. Atrophy of the retina and papilla may follow on the preceding inflammation. See Plate 14.

Course. In the majority of cases there are no uræmic convulsions at all. After a few days or a week or two improvement sets in, often quite suddenly. The volume of urine is greatly increased as the dropsy disappears; the blood pressure falls to normal. The albumin and blood disappear more gradually, small amounts being passed for weeks afterwards.

But the course of acute nephritis may be less favourable in several ways. In a small proportion of cases death follows rapidly from uræmia.

In other cases the symptoms may continue. It has already been mentioned that there is derangement of all the renal functions during the acute attack, but certain of these recover first. In some cases there may be early diuresis and disappearance of œdema, but the patient still remains ill. The percentage of urea in the blood remains high, or if this is not greatly raised, the power of the kidneys to concentrate urea is deficient. The diastase in the urine is low. The volume of urine is normal or increased. It contains albumin, but not in very large amounts. Such is the picture of the *azotæmic* type of nephritis, and it eventually leads to secondary contracted kidney.

On the other hand, the œdema may continue. The percentage of urea in the blood soon becomes normal. The volume of urine is decreased, but the percentage of albumin is large. Such cases conform to the *hydræmic* type of nephritis, and the term *nephrosis* has been used for them on the supposition that they showed no tendency to progress towards secondary contracted kidney with cardiac hypertrophy, etc., and that the urea concentration was normal. But there is no justification for this distinction, and the writer has found in some typical cases that the "rate of urea output" and the "blood urea clearance" were below normal, even though the "urea concentration" was apparently high. The case eventually becomes one of subacute glomerulo-tubal nephritis.

In yet other cases the œdema and urinary symptoms clear up entirely; there remains only a raised blood pressure without renal impairment.

Finally, there are two other groups: in one of them there is persistent slight albuminuria from a leaky kidney without casts or signs of renal impairment; in the other the patients suffer for years after from intermittent hæmorrhagic nephritis, also without signs of renal impairment, and brought on by a coryza or other acute infection (17).

Diagnosis. This rarely presents any difficulty. The sudden appearance of a general dropsy, with albuminuria or hæmaturia, in one previously quite healthy, or recovering from scarlatina or other fever, can scarcely be mistaken for anything else. If there is a small quantity of albumin only in the course of an acute disease, this may be due to a change in the epithelium, not usually regarded as constituting nephritis, though it is not essentially different from what actually takes place in the typical conditions. In pyelonephritis there is usually pain in the loin and the urine contains pus cells, while albuminuria is slight.

Prognosis. It is, on the whole, favourable, as between 60 and 70 per cent recover completely (17). The unfavourable indications are excessive dropsy,

very scanty or suppressed urine, high urea in the blood, very high tension of the pulse, asthenic uræmia, or the later condition of feeble pulse with obviously failing heart, hydrothorax, and serous inflammations. But there are scarcely any of these serious dangers from which recovery may not take place, and sometimes, after living for months on the verge of death, the patient may ultimately get quite well. The prognosis of hæmorrhagic nephritis is good; because there is presumably a free flow of blood through the kidneys.

Prevention. It has been found that the administration of alkalies (up to 200 grains a day) during convalescence in scarlet fever, will prevent, in most cases, the onset of nephritis, and the same preventive measure might well be used in acute tonsillitis, when nephritis is to be feared (36). There is some evidence that if a septic focus can be found, its removal prevents future attacks (37).

Treatment. Rest in bed and warmth are essential. Various diets have been recommended. The usual diet is confined to milk, farinaceous foods, fruit and vegetables, while the volume of fluid is limited to the pint or $1\frac{1}{2}$ pints of milk allowed. Some physicians, in the early stages, restrict the diet drastically as regards protein, chloride and fluid in the hope of bringing about an early diuresis and cure. For the first day or two glucose in $\frac{1}{2}$ pint of water will be allowed for a child, with barley sugar extra to suck; then fruit, vegetables and some cereals, and salt-free rusks, butter, cream and jam. Sufficient alkali in the form of sodium bicarbonate and potassium citrate—in equal parts—should be ordered to keep the urine just alkaline. Enough fluid should be given to allay thirst, though this is probably not distressing when there is marked œdema. Another method is to give fresh fruit and vegetables such as tomatoes and raw carrots, without added water at first, and as soon as the œdema decreases, the yolks of three eggs, given with sugar and orange juice, and meat, including liver, and then salt-free rusks and butter (38). Other physicians have tried the opposite plan of a high protein diet (meat, fish, chicken, eggs, plasmon) so as to obtain the diuretic effect of the urea formed in metabolism, or extra urea has been given to drink with honey and fruit juice. In this diet alkali as above should also be given.

During convalescence iron should be given to restore the condition of the blood, but it is not well to use it in the early stages (*see* p. 431). The treatment of dropsy is considered later. Where the tonsils are septic, it is reasonable to remove them, and this has been carried out successfully during the acute nephritis, though this is not advised; other septic foci should also be dealt with.

Acute Uræmia. The onset is heralded by a rise of blood pressure and frequent readings are desirable. Bleeding from the arm will often prevent convulsions, and 10 to 20 ounces may be removed without danger, though it is, as a rule, undesirable that patients with pronounced renal disease should lose much blood. A valuable method of arresting the convulsions is by lumbar puncture. This was definitely established in trench nephritis; but there is some danger of sudden death from a pressure cone formed against the edge of the foramen magnum, as in cerebral tumour. A recent method is to inject a 25 per cent. solution of magnesium sulphate intravenously, the dose being 0.2 c.c. per kilogramme of body weight. 50 per cent. glucose injected intravenously may counteract the cerebral œdema by increasing the osmotic pressure of the blood. Sedative drugs, *i.e.* chloral hydrate, 5 to 15 grains by mouth, four-hourly, or 30 grains per rectum; or a few whiffs of chloroform may be used to supplement the former methods. In convulsions the patient's tongue should be protected as in epilepsy, by placing a piece of stick between the teeth.

Acute Focal Nephritis. This is a form of acute nephritis now recognised, where there are patchy changes in the kidney, with resulting hæmaturia and/or albuminuria and casts, but there is a sufficient extent of healthy tissue to allow of all the excretory functions being carried out, so that there is no œdema or other symptoms. The "febrile albuminuria" of acute tonsillitis may be an example of this disease. The immediate prognosis is very good; but it is

impossible to be certain that in some cases the disease may not be the beginning of a secondary contracted kidney. The treatment is the same as acute diffuse nephritis. The name "focal nephritis" might suggest that the disease results from focal sepsis in the tonsils, etc.; but the term is not used in this sense. Of course, focal sepsis may cause either acute diffuse nephritis or acute focal nephritis.

SUBACUTE GLOMERULO-TUBAL (TOXIC) NEPHRITIS

(*Chronic Parenchymatous or Tubal Nephritis, Large Mottled or White Kidney*)

Ætiology. This diffuse type of nephritis may appear as a sequel to the acute stage, but its onset may be so insidious that the inflammatory changes in the kidney reach this stage of development before the diagnosis is made at all.

Morbid Anatomy. The *large mottled or white kidney* receives its name according as hæmorrhages or fatty changes predominate. The two kidneys together may weigh as much as 800 grammes; often they weigh 500 grammes. The surface is smooth, and the capsule strips easily; it is of yellowish or greyish-white colour, and is covered with venules radiating from a central point (stellate veins). On section, the cortex is broader than normal, of the same colour as the surface with an appearance of coarse striation, while the pyramids are more or less dark red. Here and there are red spots, due to hæmorrhage. *Microscopically*, the glomeruli show evidence of progressive inflammation. There is proliferative glomerulitis with obvious lobulation of the tuft, which may be swollen; there are adhesions between the tufts and the capsule. There is proliferation of the endothelial cells lining the capsule, so that a *demilune* is formed, and the lumen of the glomerulus may be partially or entirely obliterated. The tuft may eventually become hyaline in whole or in part. This hyaline necrosis is quite different from the focal embolic nephritis of infective endocarditis. Marked changes are seen in the convoluted tubules, similar to those described in acute nephritis. The distension of the tubes with opaque material forming casts, and the compression they exert on the vessels, account for the white or grey colour of the cortex. An increase of interstitial tissue which is partly œdema and partly due to an active proliferation of fibroblasts is widely diffused through the cortex and the intertubal tissue is irregularly infiltrated with leucocytes.

Symptoms. If this stage of glomerulo-tubal nephritis follows directly on an acute attack, there is a continuance of the symptoms already described: general dropsy, effusion into the serous cavities, scanty albuminous urine. In other cases there may be an apparent recovery from the acute attack, and after an interval the symptoms recur.

In cases where the onset is insidious, pallor, loss of appetite, nausea, headache, and frequent micturition are the first signs, and then œdema may be observed in the lower extremities at night, and around the eyelids in the morning. The dropsy gradually increases.

In advanced cases the dropsy becomes general, and the skin of the whole body is œdematous. The face is full and rounded; the eyelids are distended, and almost close the eyes; the limbs become enlarged, shapeless, and remind one of bolsters; the trunk is enlarged; the loose skin of the penis and scrotum is so stretched that the prepuce looks like a bladder, and the scrotum may attain the size of a foetal head. Wherever slight pressure is applied, as by the finger of the doctor, or by the bands, strings, or folds of clothing, it produces by the displacement of the fluid a deep impression, which is only slowly effaced by the return of the fluid. This is called *pitting on pressure*. Even then, the influence of gravitation on the distribution of the dropsy may be seen, for if the patient lies for any length of time on one side, the arm of that side will become more swollen than the arm which is uppermost; and the same will happen to the side of the face. When this general dropsy, or *anasarca*, is present, there is, as a rule, some effusion into the peritoneal cavity (*ascites*), into one side, or more

frequently both sides, of the chest (*hydrothorax*, dropsy of the pleura), and it may be into the pericardial sac. Of these the first is perhaps most often recognised, while the pericardial and pleural effusions may be comparatively slight. There may be œdema of the lungs which gives rise to no physical signs but only to dyspnoea, and also œdema of the pharynx and larynx. As in acute glomerulotubal nephritis these patients occasionally suffer from acute uræmia from cerebral œdema.

If incisions be made into the skin, or if one or more Southey's drainage tubes be inserted, a quantity of fluid will drain away, which may amount to 8 or 10 pints in a few hours, and the dropsical limbs will rapidly get smaller. The fluid is colourless, of low specific gravity (1,007 to 1,012), and contains a small quantity of albumin, inorganic salts, and urea. A feature which is constantly present in renal dropsy is a high degree of pallor—the lips are almost colourless, the cheeks are pallid, and the whole body has a waxy whiteness. This is often not due to anæmia, but to the distension of the skin and subcutaneous tissues.

The urine in parenchymatous nephritis is scanty, highly albuminous (up to 20 or 30 parts per 1,000), and contains casts of all kinds; fatty or lipid casts are numerous in the cases of large white kidney with much fatty or lipid degeneration of the renal epithelium. They are accompanied by leucocytes, loose epithelial cells, and granular *débris*. In some cases the urine contains much blood.

In the blood the cholesterol is increased, while the urea (also non-protein nitrogen) varies from normal up to fully uræmic figures, *e.g.*, over 0.10 per cent. In long-standing cases cardio-vascular changes may be present, as in secondary contracted kidney. The retinal changes described under Acute Nephritis are present in some cases. Extensive œdema of the retina may lead to its detachment.

In chronic parenchymatous nephritis, as also in acute nephritis, there is a tendency to inflammation of the serous membranes. Pleurisy is the most common; pericarditis is often the precursor of a fatal termination; acute peritonitis is perhaps more rare, unless it follows tapping the abdomen. Bronchitis is a common, and endocarditis an occasional, complication; pneumonia not infrequently occurs towards the end. Ulcerative colitis is rather a characteristic complication. Several lesions of the skin may complicate Bright's disease—namely, (1) pruritus and urticaria, the former especially in early stages; (2) eczema; (3) an acute general dermatitis, with free desquamation, not unlike exfoliative dermatitis; (4) patches of erythema affecting the dropsical limbs; (5) erysipelas; (6) purpura or hæmorrhage, followed by necrosis and ulceration, conditions which have also been observed in the alimentary mucous membranes; and (7) very rarely the skin has the appearance of having been dusted with flour or pounded sugar. This is probably due to evaporation of the sweat, leaving crystals of salt on the skin.

Course. In the majority of instances, the disease is fatal. Death is in most cases due to complications, such as pleurisy, pericarditis, pneumonia, œdema of the lungs, œdema of the glottis, increasing dropsy, heart failure, or inflammation or sloughing of the skin; and this commonly occurs in from six to eighteen months, though some cases go on for two or three years. Uræmia is not commonly by itself the cause of death. In a few instances the disease may disappear completely. In long-standing cases the various changes characteristic of secondary contracted kidney may occur.

Diagnosis. When acute nephritis changes into chronic parenchymatous nephritis there is a gradual transition, so that a distinction between the two clinically is rather artificial. From four to six months is usually regarded as the duration of the acute disease, so that chronic parenchymatous nephritis would be diagnosed if the disease had lasted longer than this. There will be no difficulty in differentiating it from secondary contracted kidney. It might be confused with lardaceous disease or primary heart disease with albuminuria. From

lardaceous disease it is distinguished by the absence of such causes as prolonged suppuration, phthisis, or syphilis, and by early scantiness of urine and abundant deposit. The similarity between this and heart disease may be close, especially when there is much œdema in the latter case. The presence of abundant casts in the urine is an indication of nephritis. The history, the general character of the dropsy, and the large quantity of albumin will help to distinguish primary renal disease from secondary albuminuria.

Treatment. This is not essentially different from that of acute nephritis. Rest in bed and warmth are essential. Where there is nitrogen retention, it is reasonable to employ a rather low protein diet as described in the next section.

Edema has been successfully treated by giving alkalies in sufficient amount to raise the alkaline reserve of the blood to a normal figure; but some cases are intractable and the administration must be carried out with caution. The alkalies used are a mixture in equal parts of the four salts: potassium, sodium, bicarbonate and citrate, and the amount given per day may be increased up to 1,000 grains or more; frequent blood examinations are desirable and sometimes the œdema increases at first. Caffeine and theobromine are best avoided.

Diminution of the dropsy is sometimes obtained by the use of a diet as free as possible from sodium chloride, as suggested in the provisional theory of Bright's disease. Indeed, healthy persons have sometimes had œdema from eating excessive quantities of salt, because water will be retained with the salt to keep the body fluid isotonic. Treatment along the lines of Epstein's theory may also be tried, and remarkable results in lessening the œdema and promoting diuresis have been obtained. The diet given is very rich in protein, with an almost entire absence of fat. A little carbohydrate is allowed. It consists of lean meat, lean ham, whites of eggs, oysters, jelly, lentils, split peas, green peas, rice, oatmeal, skimmed milk, coffee and tea, salt in moderation, and fluid as reasonably desired. This treatment may do good, not because of any increase in the plasma proteins, but because of the increased amount of urea produced and an even more effective way of producing diuresis is to give urea in 15-gram doses by the mouth. The probable explanation is that the increased urea content of the tubal fluid hinders reabsorption of water at the lower end. Where there is nitrogen retention it is better to employ urea rather than a rich protein diet, since it is probable that the latter predisposes to uræmia. Success has been claimed for thyroid treatment, especially as it has been found that the basal metabolism is often low.

Other long-practised methods of treating œdema are by purgation with 20-40 grains pulv. jalapae co., senna or mag. sulph., and by diaphoresis. Diaphoresis should be promoted by hot-water bottles or by the hot-air bath. The *hot-air bath* is administered by raising the bedclothes from the patient by means of a low cradle and fitting them close about his neck and round the sides and end of the bed. The heat may be supplied by a number of electric light bulbs placed inside the bedclothes or by burning a spirit lamp under a funnel connected with a tube which leads under the clothes. The exposure should be from fifteen to twenty minutes at 120° F.; but it is desirable to take the temperature of the patient as well, as it may be inconveniently raised, if free sweating does not occur. In this case the diaphoretic drug, nitrate of pilocarpine, in a dose of $\frac{1}{8}$, $\frac{1}{4}$, or $\frac{1}{2}$ grain, may be injected subcutaneously.

In extreme dropsy, especially where the skin is tense and threatens to become inflamed or to slough, the dropsical fluid may be removed under antiseptic conditions, either by small incisions with a lancet or punctures with a needle, or by the use of Southey's tubes. Two or more of these may be placed in each leg, and by this means several pints of serum may be withdrawn in a few hours; the tubes should be removed after six hours to prevent sepsis, but drainage may continue through the punctures. Only occasionally, in extreme cases, is it desirable to tap the abdomen or to aspirate the pleural cavity.

Anæmia in prolonged cases should be met by the use of iron preparations (*see* p. 431). In the more chronic forms, with albuminuria but little dropsy, benefit may be derived from residence in warmer climates—Bournemouth or Tenby in the British Isles, the south of France, Italy, or Egypt.

Cases of chronic Bright's disease have been treated by Edebohls in America, by exposure of the kidney, decapsulation, and fixation of the organs; but the benefit of this surgical treatment is very doubtful. Cases of parenchymatous nephritis are most suited to this procedure. Septic foci should also be removed, particular care being taken to exclude sinus infection.

CHRONIC GLOMERULO-TUBAL (TOXIC) NEPHRITIS

(*Secondary Contracted Kidney*)

This type is called "secondary," since it arises as the result of inflammation of the kidney. It is often spoken of as contracted white kidney or small white kidney to distinguish it from the red granular kidney described next; but this method of differentiation is not good because the most chronic type of secondary contracted kidney in middle age is red in colour. Histological studies have shown that there are two different types of chronic glomerulo-tubal nephritis: (1) In the *diffuse* type (chronic nephritis acris), the presence of acute or subacute toxic nephritis associated with much œdema has usually been noted from two to ten years previously, so that the kidney has presumably passed through the stages described under acute and subacute glomerulo-tubal nephritis in a variable number of years. (2) In the *reticular* type (nephritis repens), the patient may have had an acute attack of nephritis, which has apparently completely cleared up, and many years later symptoms pointing to the last stages of granular kidney are observed; but more often there is no history of any acute disease at all; the kidney changes are believed to have arisen insidiously from chronic inflammation lasting for years. The term *nephritis repens*, or creeping nephritis, has been suggested for this type from the histological picture, which suggests an inflammatory reaction with its resulting scarring that has been creeping insidiously through the kidney, leaving portions unaffected. Nephritis repens is broadly divisible into two groups: (a) there is the nephritis repens of childhood and early adult life. In these cases, as also in chronic nephritis acris, a variable amount of arterio-sclerotic change (ischæmic nephritis) is present, as described later, but it is not usually marked, and cases of war nephritis have resulted in this type of kidney without any cardio-vascular changes at all. In rare instances this type of nephritis repens has been described in children, associated with delayed rickets and infantilism; (b) there is the nephritis repens of middle age, 35–66 (average 47·7 in 15 cases), where the inflammatory process is extremely chronic and the arterio-sclerotic process is very marked. The blood pressure is much raised, and the œdema which is often present has the distribution characteristic of heart failure (24). Death may take place from heart failure, cerebral hæmorrhage or uræmia, or a combination of these. The following clinical account does not apply to these cases.

Morbid Anatomy. In the *diffuse* type the kidney is normal or a little on the small side. The capsule strips with moderate ease and the surface is smooth or finely granular and contains flecks of opaque yellow lipid, which are seen particularly well on section. The demarcation between the cortex and medulla is blurred. Microscopically, the glomeruli show proliferative glomerulitis and hyaline necrosis and proliferative capsulitis in varying degrees. The interstitial tissue in general shows areas of dense fibrosis, enclosing atrophied tubules and small islands of less dense fibrosis, enclosing dilated tubules. There is infiltration with lymphocytes, plasma cells and polymorphonuclear leucocytes in smaller number. The naked eye appearance of the kidney of *nephritis repens* (*reticular* type) is variable; it may resemble that already described, or it may be very

considerably reduced in size with obvious granulations, and certain forms are extremely scarred and irregularly lobulated. On section, the cortex is pale and the medulla often pink, and the demarcation between the two is blurred. Lipoid deposits are usually obvious; in the very chronic forms met with in middle age the colour is dark red, so that to the naked eye the kidney resembles the arterio-sclerotic kidney described next. Microscopically, the fibrotic areas which contain the damaged glomeruli and atrophied tubules are spread through the kidney in a coarse reticular fashion, surrounding large islands containing dilated tubules, which show a considerable amount of regenerative hypertrophy. Lipoid deposits are often seen, and there is sometimes hypertrophy of the surviving glomeruli. There is general infiltration of the fibrotic areas with lymphocytes, plasma cells and a few polymorphonuclear leucocytes. A variable degree of arterio-sclerotic change, the nature of which is described in the next section, is usually but not always present in both diffuse and reticular types. It tends to be more marked in the long-standing cases.

It is clear that nephritis repens is identical with the "contracted granular kidney" of Bright's disease. The writer has long believed that the smallness of these kidneys is due to their being attacked in childhood before they have reached adult size. This view is borne out by Miss Russell's observations (24). If the weights of the kidneys in her series are plotted against the body weight or height, then for a given weight or height the kidneys of the young adult are usually smaller than those of the middle aged, even though the most chronic cases are included in the latter group.

Pathology. There are two ways in which the body compensates for the loss of excretory function in renal disease. In the first place, the arterial pressure is raised by means of a hypertrophied heart and constricted arteries, so that filtration through the impaired glomeruli takes place under pressure. In the second place, the concentration of urea in the blood is increased, and this facilitates its excretion by the kidney, so that a balance takes place, the output of nitrogenous substances corresponding accurately with the amount in the food. The concentration of urea is normally 20 or 30 milligrammes per cent. Values of 100 milligrammes and over are frequently found in this disease when the patients are up and doing their ordinary work. Any great increase in the protein of the food throws more work on the kidney, and this is only performed by some additional retention of urea, so that the percentage of urea in the blood is still further increased. The balance between intake and output becomes re-established, the kidney responding to a higher threshold value of urea in the blood. The importance of limiting the protein of the food will be at once evident.

If the lesion progresses the urea in the blood becomes higher and higher. The same thing will be caused by an acute attack of nephritis supervening on the chronic condition. Characteristic symptoms of intoxication, called *asthenic* or *chronic uræmia*, appear when the concentration of urea is too high. These may begin when the urea is about 200 milligrammes per cent. In the fully developed uræmic condition values for the urea of 300, 400, or 500 milligrammes per cent. have been observed. Besides urea, non-protein nitrogen, creatinine, uric acid, phosphoric and sulphuric acids accumulate in the blood, so that the alkali reserve is lowered (27). The alveolar CO_2 is also diminished, but not in proportion to the accumulation of other acid in the blood, so that the acidity (hydrogen ion concentration) of the blood is increased (*acidæmia*). Other unknown acids and metabolites may also be present in the blood. There is evidence that the acidæmic state is not by itself responsible for uræmic coma, because acid values as high have been observed in other patients non-comatose. It is certainly not due to the urea, which is a relatively harmless substance when taken in large doses by the mouth. It might be due to poisoning by excess of the SO_4 or PO_4 ions; but it is reasonable to regard the muscular twitchings as essentially similar to *tetany* (*q.v.*), especially as the calcium in the blood is low (28). Air

hunger or extreme hyperpnœa is the consequence of the acidæmia, the CO_2 in the alveolar air and blood being lowered by this means. In a case of pure uræmia, due to the removal of a solitary kidney, these further biochemical changes were found before death: fall of blood calcium, chloride, hæmoglobin, and plasma albumin, and increase of plasma globulin and ammonia. The blood cholesterol remained normal (29).

Chronic uræmia is a characteristic mode of termination in secondary contracted kidney, but it is not peculiar to it. It may occur in arterio-sclerotic kidney occasionally, and in pyelonephritis, particularly where there is suppuration in both kidneys, in polycystic disease, bilateral renal calculus, and occasionally in acute nephritis.

Symptoms. In the diffuse type considerable œdema is usually present in the terminal stages; but in the nephritis repens of young people there is usually no œdema, though slight puffiness under the eyes is not uncommon. In both types the volume of urine is increased, especially at night, and the patient has to get out of bed one or more times to pass water. This is to be regarded as a compensating mechanism, since the kidney excretes at night what it cannot get rid of in the daytime. It is more marked when the protein content of the diet is high. In the final stage the urine is pale and of very low specific gravity, 1,005 to 1,012. Albuminuria is present, but the percentage of albumin is never as great as with large white kidney. Casts and blood cells are seen on examination of the deposit. The blood pressure is raised, but it is not usually so high as in cases of arterio-sclerotic kidney. The heart shows evidence of hypertrophy (*q.v.*). There is marked secondary anæmia.

"Albuminuric retinitis" is very characteristic of secondary contracted kidney. Owing to the vascular changes always present in this condition, the retinal changes often resemble rather closely those which have already been described under arterio-sclerosis (*see* p. 302). On the other hand, the larger, pale, soft-edged areas, or cotton-wool patches (*see* p. 522), are sometimes seen (*see* Plate 14, p. 303). Bright patches of exudation, showing fatty changes microscopically, are sometimes arranged as a star-shaped figure in the macular region.

The patient may continue for years with varying health. In some cases there is nothing at all to suggest the presence of disease until uræmia suddenly comes on. This is of the chronic or asthenic type.

Asthenic Uræmia. The patient complains of feeling weak and sleepy, of nausea, which may be accompanied by vomiting, and of headache. There may be cramps and tingling sensations. Periods of restlessness alternate with stupor. Twitching of the muscles of the face are seen; they may also affect the arms, legs and trunk; but there are no convulsive attacks as in sthenic uræmia. The pupils are contracted, the temperature of the body falls, the breathing is slow, panting, and laborious, the mouth and tongue are dry, and there is great thirst, and there may be troublesome vomiting. The muscular twitchings continue, and the patient becomes restless, indifferent, and drowsy, and coma eventually occurs. As coma develops the breathlessness gives rise to deep hissing respirations; the air hunger may be just as marked as in diabetic coma. The breathlessness increases in proportion as the acid accumulates in the blood. Sudden attacks of breathlessness, sometimes called "renal asthma," have been described, particularly at night. Cheyne-Stokes breathing has also been described. Since a raised urea content in the blood is regarded as the criterion for true asthenic uræmia, these two latter types of respirations are not uræmic, but are due to acute pulmonary œdema. They are commonly seen in cases of arterio-sclerotic kidney (cardio-renal disease), and the cases described by Lewis and others (*see* p. 255), were probably of this nature, since the blood urea was always less than 100 milligrammes per cent., far below the true uræmic value. Further observations have shown that there is no increase of fixed acids in the blood in these cases (25, 26). It is probable that in the past the term *uræmia* was

held to cover a number of different states, and it is only with the advent of methods of biochemical investigation that these states are in process of being differentiated from one another. When the symptoms of uræmia are less pronounced the condition is sometimes called *latent uræmia*, a name which has also been given to the results of suppression of urine from obstruction of the urinary passages (*see* p. 549).

Death may also be due to secondary infections, *e.g.* pleurisy, pneumonia, pericarditis, gastro-enteritis leading to severe vomiting and diarrhœa and ulcerative colitis. Hæmorrhages which are of toxic origin due to renal failure (as opposed to those due to high blood pressure and degenerate arteries), may take place from mucous membranes or into the brain, and not uncommonly play their part in causing death, and any of these terminal events may accompany uræmia. But secondary infection is not such a common mode of termination as it is in subacute toxic nephritis.

Diagnosis. This depends on finding a dilute urine containing albumin associated with impairment of renal function, with but little tendency to œdema. The differentiation of intestinal obstruction and uræmia may be difficult as there is a rise of blood urea in both, but in intestinal obstruction there is alkalosis with a high or normal alkaline reserve, while in uræmia the alkaline reserve is low.

Prognosis. This is bad in the developed disease. The tests most valuable in estimating the gravity of the case are the examination of the retinæ and the estimation of kidney function. If there is well-marked retinitis, the patient will probably not live longer than two years. If the blood urea is permanently above 100 milligrammes per cent., uræmia may supervene at any time. Patients may live many years if the blood urea is below this figure, especially if the urea concentration test is fairly satisfactory.

Treatment. After the removal of any condition which can be safely regarded as the cause of the condition—*i.e.* alcohol, lead, constant exposure to cold, septic foci, etc.—the objects should be (1) to diminish the call upon the excretory power of the kidney; (2) to reduce the strain upon the heart and vessels; (3) to remove anæmia; and (4) to treat special complications as they arise.

The most important part of treatment will be to remove as far as possible strain from the kidney, and prevent the retention in the blood of acid products of protein in metabolism, so characteristic of uræmia. The metabolism of food yields varying amounts of acid and basic breakdown products, and foods may be grouped according as the yield of acid or of base is in excess. Vegetables and fruit, including lemons, provide an excess of base over acid as the result of metabolism, whereas eggs, fish, meat, biscuits, oatmeal, rice and wheat produce an excess of acid over base. Milk probably produces a slight excess of base over acid. Hence the advantage of choosing a lacto-vegetarian diet with sugar. But since very little protein is required to make good the wear and tear of the body, and the greater part of the protein taken on an ordinary diet is used merely as a source of energy, while the final breakdown products have to be excreted by the kidney, it is also advisable to restrict the amount of protein in the diet. Eggs, fish, meat, poultry and game, etc., should be entirely excluded. Bread, biscuits and cereals, except oatmeal, may be allowed in moderate amount, because their protein content is low, while the fact that they produce excess of acid over base may be remedied by prescribing sufficient doses of alkali to get the urine neutral (*see* Treatment, Subacute Toxic Nephritis). The amount of milk should also be restricted because its protein content is relatively high (*see* List D on p. 475). However, a warning is necessary, because when considerable amounts of albumin are being lost in the urine it is necessary to make allowance for this in the dietary. The average amount of albumin passed during the twenty-four hours should be determined, and an additional 5 to 10 grams of protein allowed per diem, so as to cover amply the loss from wear and tear of the body. Fats in the form of cream in limited

quantity, butter and olive oil, may be added to make up a sufficient diet ; weak tea or coffee may be allowed. A periodical fast day may be instituted, if the nutrition is good. Alcohol should be entirely stopped, or amount at most to a glass of claret or dry sherry daily. Complete rest may be enforced when symptoms are serious, particularly if there are breathlessness when the patient is walking about and attacks of angina pectoris. At all times over-exertion and strain should be avoided. Exercise should be taken within the capacity of the heart. The patient should be warmly clothed, and residence in a genial climate is of great benefit.

Such hygienic measures may tend of themselves to lower the blood pressure. It must be remembered that the high blood pressure is probably itself in many cases a compensatory mechanism, so that the attempt to influence it directly with drugs, even if partially successful, may be bad practice. However, drugs may be used for this purpose if there is troublesome headache. Nitro-glycerine ($\frac{1}{100}$ minim once or twice daily and gradually increased), or sodium nitrate, or erythrol tetranitrate may be used. Antipyrin, caffeine, and phenacetin are also useful.

Preparations of iron should be given for the anæmia (*see* p. 431).

Among the complications which require treatment are uræmia, vomiting, cardiac dilatation and failure. In uræmia the chief indication is to get rid of the excessive protein catabolites from the blood. For this purpose sweating should be promoted. A hot-air bath is sometimes useful, and pilocarpine injections have been employed. The bowels should be made to act freely, those purgatives being used that produce large watery evacuations, such as jalap. Irrigations of the colon may be used. Bleeding has often been of benefit, and this has occasionally been followed by blood transfusion from a suitable donor. Great care should be taken to see that the flow of urine remains free. Plenty of fluid should be taken by mouth. Intravenous injections of saline may be given if the blood pressure suddenly begins to fall. It is reasonable to add some sodium bicarbonate to the fluid to combat the acidæmia, and this drug may also be given by mouth.

For vomiting, effervescing mixtures, dilute hydrocyanic acid, a few drops of tincture of iodine in water every hour, or a cold compress or blister to the epigastrium may be tried. For the cardiac symptoms, which result from dilatation and feeble contraction of the ventricle, digitalis should be given, the bowels should be kept open, and generally the case should be treated like one of heart disease.

ARTERIOSCLEROTIC KIDNEY

(*Gouty, Red Granular or Primary Contracted Kidney ; Ischæmic Atrophy of the Kidney*¹ ; *Cardio-renal Disease*)

Ætiology. Arteriosclerotic kidney is the end result of that arteriolar proliferation which is called diffuse hyperplastic sclerosis, which primarily causes hyperpiesia ; and the ætiology is the same as that of hyperpiesia (*see* p. 301). A mild form of this disease is not uncommonly found at post-mortem in elderly people, and this has been called *senile arteriosclerotic kidney* ; but this does not require separate description, except to mention that there is no cardio-vascular hypertrophy, so that the blood pressure is not raised. Arteriosclerotic kidney may be complicated by the supervention of an acute or subacute toxic nephritis.

Morbid Anatomy. The average weight of these kidneys is about normal ; but they are frequently somewhat reduced in size, though they are rarely as small as the secondary contracted kidneys of nephritis repens ; they may be large. Some specimens show no macroscopic abnormality except thickening of the arteries. In the majority the capsule is densely adherent, and, if stripped off, carries with it small portions of renal tissue ; the whole surface of the kidney is then seen to be covered with minute elevations (granulations) of $\frac{1}{16}$ to $\frac{1}{8}$ inch in size, consisting of the more healthy tissue, with intervening depressions due

¹ This term is preferable to "Ischæmic Nephritis," which has been recently introduced (24), because the changes are not regarded as inflammatory.

to scarring, and here and there may be cysts varying from $\frac{1}{8}$ to $\frac{1}{4}$ inch in diameter, and containing a clear fluid or colloid material. In some kidneys the scarring of the cortex is very uneven, deep clefts or pits appear at intervals on the outer surface, and the capsule is adherent to these, while the surface in between the clefts is smooth. The colour is mostly brownish-red, hence the name red granular kidney. The whole organ is tough; on section the cortex may or may not be narrow; the demarcation between cortex and medulla is usually good.

Microscopically, the arterioles show diffuse hyperplastic sclerosis (*q.v.*) with thickening of their coats; the thickening may be so great that many of them become obstructed and this leads to collapse and ischæmic atrophy of the glomeruli and tubules supplied by them, which then form hyaline scars. The earliest glomerular change is a thickening of the basement membrane of Bowman's capsule, which spreads round and causes narrowing of the neck of the tuft so as gradually to cut off its blood supply. The whole glomerulus appears to shrink, and this is especially the case with the tuft, which loses its shape and is flattened and finally becomes invaded by small lymphocytes, which break through the fibrous investment and demilune which surrounds it. At the same time there is intense hyaline fibrosis of the interstitial tissue in the immediate neighbourhood. The progressive disease of the smallest renal arteries leads to numerical increase of the areas of scarring or contraction.

Symptoms.¹ The onset of arteriosclerotic kidney is generally quite slow, and marked by few distinctive features. Often, indeed, the kidneys are found to be granular in patients who die of other diseases, or a patient is struck down by cerebral hæmorrhage without any symptom having attracted attention to the condition of these organs. Amongst early symptoms, which, occurring in a middle-aged person, should make one think of granular kidney, if not accounted for in other ways, are recurring or persistent headache, shortness of breath, Cheyne-Stokes breathing, especially at night, general weakness, and œdema of cardiac type. Occasionally no symptom may be sufficiently prominent until the sight is affected by arteriosclerotic retinitis, and the patient's eyes are examined with the ophthalmoscope. The blood pressure is usually much above the normal and higher than in the secondarily contracted kidney; values of 300 mm. are sometimes found for the systolic pressure. The diastolic pressure is also raised, but not in proportion. The urine is normal except for a trace of albumin and a few red cells, leucocytes and hyaline casts. The rate of urea output is usually normal, but may be a little deficient.

Hæmorrhages may occur owing to the high blood pressure and to the changes in the smaller arteries. In addition to retinal hæmorrhages, epistaxis is common and purpura and bleeding from the stomach and bowel may occur. The most important is cerebral hæmorrhage, which may cause death. It may take place in the neighbourhood of the basal ganglia, in the pons or medulla, or hæmorrhage may take place into the meninges.

The commonest cause of death is failure of the hypertrophied heart. This is frequently accelerated by myocardial degeneration. Various grave cardiac irregularities may occur—auricular fibrillation, pulsus alternans, heart block. The mitral valve becomes incompetent, and eventually the complete picture of a failing valvular disease may be developed, with a mitral systolic murmur, engorgement of the lungs and liver, ascites, dropsy of the lower half of the body. The urine is altered in the same manner as it is in a failing valvular disease—that is to say, it becomes scanty, high-coloured, and the albumin increases and the casts become granular. The pulse may for some time retain its hardness, but eventually there is a fall of blood pressure.

As the case progresses there is commonly some slight evidence of renal failure, as indicated by a blood urea of 40 to 50 milligrammes per cent., and the rate of

¹ The symptomatology of Arteriosclerosis and Hyperpiesia should also be consulted.

urea output falls a little. But the renal changes are not usually important unless the case is complicated by a sudden acute nephritis, when the patient may die rapidly of uræmia (*malignant sclerosis*), but more often of acute heart failure (24).

Diagnosis. The conditions that justify a diagnosis of primary contracted kidney are a small quantity of albumin in the urine, associated with symptoms of ill-health, and evidence of cardio-vascular disturbance, such as high blood pressure, thickened arteries, cardiac hypertrophy, retinal hæmorrhages, or retinitis, and œdema of the feet.

In a more advanced stage of the patient's illness, it is often very difficult from the clinical features alone to determine whether a case is one of *primary valvular* or *myocardial heart disease* with albuminuria from congested kidneys, or one of granular kidney with secondary hypertrophy and dilatation of the heart. A localised systolic murmur at the apex may occur in both cases; diastolic or pre-systolic mitral murmurs, and much more, aortic murmurs, are in favour of primary heart disease.

In their typical conditions there can be no difficulty in distinguishing between arteriosclerotic and secondary contracted kidney: in the latter the albumin is usually abundant, and the patient is younger, the blood pressure not so high, the urine more dilute; in fact, the picture throughout is definitely renal, while in the former the symptoms are mainly circulatory.

Prognosis. This is unfavourable, but much improvement may take place, and life may be prolonged in some cases to an advanced age. The greater the extent to which the heart is implicated, the less is the expectation of life.

The **Treatment** is that of arteriosclerosis and hyperpiesia (*q.v.*). Striking results are sometimes obtained with a low protein vegetarian diet as described in the last section. The treatment of chronic cardiac disease should also be referred to.

KNOWN BACTERIAL INFECTIONS OF THE KIDNEY

BACTERIURIA AND BACILLURIA

The following organisms are found in the urine: bacilli of the enteric group and tuberculosis, *Brucella melitensis*, *Leptospira icterohæmorrhagiæ* and the ova of *Schistosomum hæmatobium*—all associated with the corresponding specific disease. Staphylococci commonly accompany genito-urinary tuberculosis or calculi, or are secondary to infarcts in the kidney. *S. albus* can be cultivated from the urinary meatus and hence a few colonies can be disregarded and the same is the case with diphtheroids. *B. pyocyaneus* is secondary to a more virulent organism. Gonococci may come from a urethritis or ruptured prostatic abscess and heavy infection of the urine may be due to fistula between the bladder and colon.

Since the kidneys excrete waste products from the blood stream it is not surprising that bacteriuria is a fairly common condition, and discussion has taken place as to whether bacteria can be excreted without there being any lesion at all of the renal epithelium. Certainly in the bacilluria of typhoid such lesions are not obvious, though it would be very difficult to exclude them if they are only microscopic. Again streptococci circulating in the blood stream as a septicæmia or from some primary focus such as inflamed tonsils may be met with in the urine, though they probably slip through the renal epithelium after lodging as minute embolic foci in the kidney. However, in most cases there is no doubt that the bacteriuria means that pyelonephritis is present, as described later, and this is especially the case with the *Bacilli coli communis*, which is the most important urinary organism and may be present in the urine in enormous numbers and yet give rise to but few symptoms. "Atypical B. Coli," usually as *B. proteus*, are associated with chronic infection in the urinary tract.

From what has been said it will be seen that in most cases the ætiology is the same as that of pyelonephritis.

Condition of the Urine. The urine is often clear when passed, but on standing it deposits a layer like mucus at the bottom, above this there is a haze or turbidity, and at the top a clear layer; or the urine is entirely turbid; and the turbidity does not clear on standing. The urine is usually *acid*, and it does not become clear either with heat and acetic acid or with alkalies. The presence of pus cells and albumin, even in small amount, proves that there is a pyelonephritis. When the urine has an offensive odour and there is pus, mucus and bladder epithelium it suggests that cystitis is present.

PYELONEPHRITIS

(*Pyelitis*)

The term *pyelitis* for this disease has been in use for over twenty years. However, there is evidence from post-mortem statistics that among these non-tuberculous infections of the kidney *pyelitis alone* is uncommon, accounting for only 7 per cent. of cases, unless there is obstruction to the urinary flow, when the occurrence is 52 per cent. (30). In fact, the disease commonly called *pyelitis* is in most cases a *pyelonephritis*, beginning in the substance of the kidney and spreading to the pelvis, and this is proved clinically by the fact that there is usually more albumin in the urine than can be accounted for by the amount of pus (or blood) present, proving that the kidney itself must be involved.

Ætiology. Pyelonephritis arises from several causes, of which the following have been recognised: (1) The action of turpentine and cantharides when given internally. (2) Gastro-enteritis, colitis, gall-bladder disease, appendicitis, febrile disorders, such as enteric and typhus fever, the exanthemata and pyæmia as well as scurvy, diphtheria, and cholera. (3) It may occur in Bright's disease and diabetes; in the latter probably as a result of the irritation by the saccharine urine. (4) Many cases are due to a definite local cause, such as the irritation of foreign bodies in the pelvis and infundibula of the kidney, especially calculi and gravel, but also hydatids, blood clots, and carcinoma. (5) Obstruction to the passage of urine may also lead to it by decomposition of the retained urine. Obstruction may be due to urethral stricture, enlarged prostate, renal or vesical calculus, and retention of urine from disease or injury of the spine or spinal cord. (6) Inflammation may spread upwards in the lymphatics outside the ureter to the pelvis in cases of cystitis and other forms of inflammation in the lower urinary passages. The fact that pyelonephritis is three times commoner in women suggests that the infection commonly spreads up from below to the kidney, from a vulvo-vaginitis, for example, which must be a common source in very young girls. (7) There is no obvious primary focus, so that it seems pretty certain that the infection reaches the kidney by the blood stream. Usually one kidney alone is affected. Such patients get well, but they often relapse.

The colon bacillus was found as the causal organism in 76 per cent. of cases, presumably owing to the propinquity of the colon; in the remainder cocci were found, including *S. aureus* (31). Streptococci and staphylococci and other organisms commonly accompany a *B. coli* infection. Pregnancy predisposes to infection, since with the usual position of the foetus the uterus may press on the right ureter, causing partial obstruction and dilatation of the pelvis above.

Morbid Anatomy. In the common form of the very acute type of pyelonephritis the organ is swollen, soft, hyperæmic, and generally infiltrated with inflammatory cells, but without abscess formation; this form may develop into gangrene. The commoner forms of kidney infection are, however, local, affect a segment of kidney substance, and may be generally described as of the infarct type. The characteristic feature is the presence of numerous yellow streaks of pus, stretching in a radial direction from the surface inwards through the cortex,

and even into the pyramids. They are sometimes wedge-shaped, or conical, with the base at the surface, in other cases simply linear. The infarct may break down into an irregular abscess cavity which discharges into the kidney pelvis. In other kidneys, where presumably the embolic infection has been less compact, the area shows up in the surface as a group of small abscesses which also appear in section in that segment of the kidney corresponding to the abscesses on the surface. There may be several patches of such purulent infiltration, the intervening portions of the kidney substance being healthy. One kidney only may be affected.

The localised infarct type of pyelonephritis is capable of healing like purulent lesions in other parts; the scar comprises a segment of the kidney substance depressed on the surface, sometimes with a local dilatation of the pelvis. Occasionally there are loculated cysts occupying a segment of kidney substance, in shape very suggestive of an origin from a septic infarcted area. Some of the cysts met with post-mortem, that are roughly classified as "congenital," have probably been caused in this way. A perinephric abscess is frequently due to a cortical abscess spreading to the perirenal tissues.

In acute *pyelitis* proper the mucous membrane is swollen, its vessels are injected; there are often small spots of hæmorrhage; sometimes the inflammation takes on a diphtheritic form, patches of membrane adhering to the surface here and there. In calculous pyelitis there may be ulceration of the surface from the presence of the stone; and such ulceration may, as already indicated, lead to perforation and perinephritis. Or if, either from the dislodgment of calculi or obstruction of the ureter by septic discharges, the inflammatory matter is confined, then a pyonephrosis results.

That type of kidney inflammation which is caused by repeated attacks of pyelonephritis and scarring, is called atrophic pyelonephritis. It may occur on one or both sides; the kidney is small, contracted, and fibrosed, and in extreme cases there may be no kidney substance left. It is sometimes extremely difficult to distinguish from the secondary contracted kidney of Bright's disease. The main distinctions are that in atrophic pyelonephritis the fibrosis and atrophy are patchy to the naked eye, and there is irregular coarse scarring of the surface. There is dilatation of the pelvis, infundibula, and calyces, with flattening of the pyramids, or one or two calyces may be alone affected. In the renal pelvis there may be, besides pus and urine, blood, calculi, or other foreign bodies which have set up the mischief; and the urinary salts may be deposited, namely, urates in acid urine, and phosphates if the urine is alkaline or ammoniacal, as it often is. In some old cases the kidney is so atrophied as to consist of little else than its capsule with septa forming cavities which contain putty-like masses, the result of the inspissation of pus and the deposit of amorphous phosphates.

Symptoms. In the mildest form of acute pyelonephritis where there are, perhaps, only one or two patches of inflammation, the symptoms may not be severe enough for the patient to call in a doctor. In the severer form there is frequently some dull, aching pain in the loin, increased on pressure, with rigidity of the abdominal muscles, or a large tender lump may be palpable in the loin. There is fever, and at times rigors and a leucocytosis. Micturition may be frequent and painful and there may be retention. The cells of the pelvic epithelium may, perhaps, be distinguished; they are conical, pyriform, or fusiform in shape. The patient may vomit, especially if the pain is severe and colicky. Where the pyelonephritis is secondary to infection elsewhere in the urinary tract, the symptoms due to the latter will also be present. In the severest form of all there may be a high continuous or remittent temperature, quick, feeble pulse and all the characteristics of the typhoid state—loss of appetite, dry brown fissured tongue, nausea and vomiting, sometimes diarrhœa, sweating, and rapid emaciation. When both kidneys are extensively affected the renal function is interfered with; there may be increased urea in the blood, acidæmia

and a typical renal œdema ; and eventually symptoms typical of asthenic uræmia may show themselves—coma, twitching of muscles and air hunger.

In the pyelonephritis of children under two years, there is a group of fatal cases secondary to infections elsewhere, *e.g.* otitis media, gastro-enteritis and pulmonary disease. In older children there may be only incontinence of urine and frequency of micturition, though local symptoms of renal disease may occur at intervals. A case of incontinence of urine in a child should always be investigated for bacilluria and pyelonephritis.

The urine in the milder cases will contain pus cells, bacteria (*see* Bacilluria), perhaps a few blood cells, and a little albumin, and is usually acid. In the severer forms the urine contains pus in notable quantities (*pyuria*). When such urine is passed it is turbid, and as it settles the pus forms a very pale yellow creamy deposit at the bottom of the glass, and mixes with the urine only just at the line of junction. The nature of this deposit can be determined by the microscope or by chemical tests, *e.g.* the supernatant liquid is poured off, and some liquor potassæ is added to the deposit ; it quickly loses its colour, becomes translucent, and changes into a viscid, ropy liquid, which falls from vessel to vessel in a more or less coherent mass. If the urine should decompose and become alkaline within the body, the pus will undergo the same ropy change, and the urine will be mixed with this viscid, glairy fluid, instead of with creamy pus. This happens sometimes in pyelonephritis and pyonephrosis, if the urine retained in the dilated pelvis at length undergoes decomposition ; and it happens frequently from the same cause in cystitis.

Purulent urine may be retained by an obstruction of the ureter, with the formation of a hydronephrosis (*q.v.*) or a pyonephrosis.

In chronic pyelonephritis and atrophic pyelonephritis the local pain and tenderness may be almost absent, so that there is difficulty in diagnosis. Apart from bacilluria the urine need not be markedly abnormal. The patient appears to have neurasthenia or chronic ill-health, and asthenic uræmia may end the scene. In these circumstances the blood pressure is not by any means always high or the heart hypertrophied.

Diagnosis. Pyelonephritis must be distinguished by the local signs, and by the presence of pus cells in the urine ; the typical urine has been described on p. 535. Uro-selectan provides a valuable means of diagnosis, because it indicates the functional capacity of the kidney and the size of the pelvis. Retrograde pyelography and cultivation of the urine after ureteric catheterisation are also employed, but not if there is cystitis.

Pyonephrosis may be confounded with the numerous swellings which occur in the right flank, and which will be alluded to under Perinephric Abscess. The latter cannot always be distinguished from pyonephrosis ; but with hydronephrosis there will not be any temperature.

The **Prognosis** depends very much upon the primary cause. Pyelonephritis without obstruction to urinary outflow, usually gets well, although it may linger on for a long time. Pyonephrosis is a serious lesion ; it may be fatal by perforation into the chest or abdomen, by exhaustion from continued discharge, or by the induction of lardaceous disease. Rarely the pus inspissates, and a cure results from the loss of one kidney. Tests for renal functions will indicate whether there is danger of uræmia.

Prevention. That pyelonephritis may supervene should always be borne in mind in the treatment of the urinary organs. In spinal cases it is necessary to try and prevent the onset of cystitis. Owing to war experience, the use of the catheter is now much restricted in these cases, since infection is introduced by such means. In cases where the spinal cord is completely divided, use may be made of certain reflexes that develop. At periodical intervals the skin is stimulated. This leads to flexor responses in the limbs and contraction of the bladder, so that the latter is completely emptied. In other cases when

cystitis is present the bladder should be irrigated with some antiseptic solution, such as salicylate of sodium (5 grains to 1 ounce), quinine (1 or 2 grains to 1 ounce), or borax (5 grains to 1 ounce); and urotropin (10 grains) or helmitol should be given internally. Continuous drainage is advisable by a catheter.

Treatment. If there is obstruction to the urinary flow little good will be done by medical treatment; the case is surgical. A continuous drainage by a catheter may be a palliative. In acute cases due to *B. coli communis*, the first treatment should be to make the urine alkaline throughout the twenty-four hours, as described under Acute Nephritis, and plenty of fluid should be taken. If this is ineffective, after two or three weeks hexamine is given in doses of from 6 to 10 grains and the urine is now made acid by prescribing 30 grains of acid sod. phosphate, separately, three or four times a day. An alternative is to give calcium chloride 15 grains in a salol capsule five times a day; but indigestion may be caused. Betaine hydrochloride 7 grains each dose is another way of giving acid. It is essential to test the acidity of the urine (*see* p. 508). When the urine is alkaline in the first place, the acid treatment should be given first. These two treatments may be alternated several times. In refractory cases, especially in children, success is sometimes obtained by establishing an artificial ketosis; carbohydrate food is removed as far as possible from the diet and fat and protein added, so that the urine gives a strongly marked Rothera's reaction. This may be continued for a week or two; but care must be taken that the child's alimentary canal is not upset by so unnatural a diet. In very chronic cases oil of sandal-wood, copaiba, and benzoic acid, or salol may be given, or hexyl resorcinol 0.3 gramme in gelatine capsules. A nutritious diet with plenty of vitamins and fresh air in the country or at the seaside are desirable. Tr. hyoscyami ℞ may be given for pain, and dry-cupping may be tried, especially if there is much blood. The mandelic acid treatment, recently introduced, is as follows: R mandelic acid gr. 45, sod. bicarb. gr. 20, aq. menth. pip. ad 1 oz. q.d.s. The urine is made acid with ammonium chloride, *e.g.* gr. 30 Ext. glyc. $\frac{1}{2}$ oz. aq. chloroformi ad 1 oz. t.d.s. With methyl red (5 drops to 2 c.c. distilled water) added to urine the colour should be orange.

METASTATIC NEPHRITIS

It is doubtful whether it is really justifiable to describe a separate disease under the term Metastatic Nephritis, considering that it has been found that pyelonephritis is, in many cases, a blood-borne infection. Actually in staphylococcal pyæmia it is common enough to find metastatic abscesses in the cortex of the kidney. If these abscesses break through into the collecting tubules and pelvis, a true pyelonephritis results; but they commonly remain shut off from the pelvis or extend so as to form a perinephric abscess. Hence a metastatic nephritis is necessarily the preliminary stage of a descending pyelonephritis, and the symptoms have already been considered. In those cases where at autopsy metastatic abscesses are found as part of a pyæmia, the symptoms are those of the pyæmia, and the renal abscesses are merely incidental.

In malignant endocarditis, metastatic abscesses may occasionally arise from the breaking down of embolic infarcts of various sizes. These are conical, but generally have a different shape from the abscesses of pyelonephritis, the base being relatively broader. However, the infarcts being often due to streptococcus viridans do not usually breakdown into pus. Embolic infarction may be indicated by pain and by blood and albumin in the urine.

PERINEPHRITIS AND PERINEPHRIC ABSCESS

Perinephritis is the term used for inflammation of the tissues around the kidney.

Ætiology. It arises: (1) From injury—such as blows, kicks, or strains. (2) From the extension of inflammation from the kidney, the pelvis of the kidney or the ureter. This may be the result of pyelonephritis, pyonephrosis,

tubercle of the kidney, or calculus. (3) From inflammation, especially suppuration, in more distant parts spreading to the perinephric tissues; for instance, pelvic cellulitis, appendicitis, abscess of the liver or spleen, caries of the spine and psoas abscess, or inflammation of the gall-bladder.

Symptoms. These are to a certain extent those which accompany other inflammatory processes. The onset may be insidious, when there is nothing but some dull aching *pain*; in other cases it will be marked by rigor, with elevation of temperature, which continues uniformly high, or is intermittent in character. The pain is deep-seated, in the loin or side of the abdomen, and radiates to the hypogastrium, groin, or genitals; that is, over the distribution of the lumbar plexus. The pain in the loin is increased by pressure, and on bimanual examination a certain amount of fulness or resistance may be felt in that region. The patient may be unable to flex or extend the lumbar spine.

As the case progresses, a more or less extensive *tumour* occupies the space between the last rib and the crest of the ilium, uniformly dull, bulging the flank, causing œdema of the loin, and perhaps fluctuating. The leg of the same side is often flexed at the hip joint, and attempted extension causes pain. Attention has also been called to the peculiar way in which a patient stands who has perinephritis, and this even when the inflammation has not reached the stage of abscess: the body is bent over to the affected side, the hip is a little flexed, and the hand rests on the same thigh. A certain resemblance to hip-joint disease is thus often assumed.

The urine is not necessarily affected; if the inflammation has resulted from inflammation of the kidney, pelvis, or ureter, pus from the perinephric abscess may pass into the urine (*pyuria*). In other cases albuminuria may occur from pressure of the abscess on the renal vein.

When pus forms, it is generally situated at first between the kidney and the lumbar muscles, and may make its way in various directions. Externally it usually points between the edges of the latissimus dorsi and the external oblique muscles; or it may pass downwards and point under Poupart's ligament. In other cases it opens into the colon, ileum or stomach; into the ureter, bladder, or vagina; or into the peritoneum, causing peritonitis. Or it perforates the diaphragm and sets up pneumonia, pleurisy, and empyema; or, without perforation, it causes pleuritic effusions, or compresses the base of the lung.

Diagnosis. The conditions that are most likely to be mistaken for perinephritis are lumbago, spinal caries, cancer and tumours of the kidney, hydronephrosis and pyonephrosis, appendicitis, diverticulitis, faecal accumulations, splenic and hepatic tumours. The careful localisation of the lesion will distinguish it from spinal caries, hepatic and splenic tumours, and appendicitis. Faecal accumulations, cancer of the kidney, and hydronephrosis are not accompanied by fever; nor is lumbago, and this is often a bilateral trouble. Exploration with needle and syringe may reveal pus.

Treatment. This is mainly surgical. Local applications and opiates will relieve pain. If pus has formed it should be let out as soon as possible.

TUBERCULOSIS OF THE KIDNEY

The kidneys may be infected by tubercle as a part of a *general miliary tuberculosis*. The tubercle appears in the form of minute grey or yellow deposits, 1 or 2 mm. in diameter, scattered irregularly, and, as a rule, rather scantily in the cortex and medulla of the kidney. A few may be seen on the surface, and others are revealed by section; they are round in shape or slightly elongated in the direction of the tubules. They present the characteristic minute anatomy of tubercle. The rest of the kidney is healthy, and, as a rule, there are no clinical symptoms attending their deposition.

The term *tuberculous nephritis* is applied to certain cases of nephritis associated

with active pulmonary tuberculosis; or it may occur in one kidney, when the other kidney is tuberculous; the urine contains albumin and casts. It is supposed to be a toxic nephritis and tuberculous lesions are absent; it may clear up with removal of the primary focus.

Tuberculous kidney proper or *chronic renal tuberculosis* is secondary to a tuberculous lesion elsewhere in the body. In most cases it arises as an infection from the blood stream; it is rather commonly associated with tuberculosis of the genital system (especially the epididymis) and of the bones and joints. It affects men more often than women; nearly three quarters of the cases occur between twenty and forty. It is quite commonly bilateral.

CHRONIC RENAL TUBERCULOSIS

Morbid Anatomy. Under this head are included almost all forms of renal tuberculosis that come under the care of the surgeon. It includes the conditions known as apical tuberculosis, ulcero-cavernous tuberculosis, tuberculous hydronephrosis, caseous tuberculosis, nodular tuberculosis, and tuberculous abscess.

The first change, in the great majority of cases, takes place at the apex of a pyramid. There is a small loss of substance surrounded by a zone of inflammation. The ulceration spreads outwards towards the base of the pyramid, and a cavity communicating with the calyx is formed; the lining of the cavity is a layer of necrotic or caseating tissue. Beyond this is a zone of inflammation which may show grey tubercles, and occasionally there is a complete zone of grey gelatinous tubercles. Outward from the zone of inflammation isolated tubercles are dotted in normal renal tissue or arranged as one or more streaks radiating to the surface of the kidney. On the surface of the kidney groups of tubercles are seen in areas corresponding to the subjacent tuberculous pyramids. One or several, or all the pyramids may be affected in different degrees. Another pathological process may now become prominent; in the wall of the calyx at its neck, or the division of the pelvis at its outlet, or in the wall of the pelvis, fibrous thickening develops and contracts until the passage is finally occluded. If now the urinary secretion in the section that is gradually being occluded is maintained, a localised cyst or partial or total hydronephrosis develops. If, on the other hand, the secretion of urine is abolished, a caseous mass surrounded by fibrous tissue is formed and the whole kidney may be converted into a mosaic of these caseous masses. The ureter is greatly thickened and rigid in a large proportion of cases. There is ulceration, necrosis, and caseation of the mucosa, and tuberculous infiltration with the formation of thick layers of fibrous tissue in the middle and outer coats. Stricture formation may affect one or several parts of the tube, and dilatation of the tube occurs above (19). In advanced cases the disease spreads to the bladder.

Tuberculous kidney occasionally heals by the formation of a ring of fibrous tissue round the focus so as to shut off completely the whole kidney, or, less commonly, a part of it; such a condition is called *closed renal tuberculosis*.

Symptoms. In the majority of cases irritability of the bladder with increased frequency of micturition is the first and for a long time the only symptom of which the patient complains. It is accompanied by pain before and after micturition. The urine in the early stage is increased in quantity; it is pale, faintly acid or neutral, and contains albumin and a small amount of suspended pus and fine white flakes. In uncomplicated cases a few tubercle bacilli are found, but no other bacteria.

Slight terminal hæmaturia is frequently observed, and an attack of hæmaturia is occasionally an early symptom. Rarely, severe attacks of hæmaturia are a prominent feature. Continuous slight loss of weight is, as a rule, observed, but there is no rapid or severe emaciation in uncomplicated renal tuberculosis. Renal pain is usually insignificant, and may be entirely absent. With severe hæmor-

rhage there may be ureteric colic from clots. Fever is absent in most cases, but a slight persistent rise of temperature to 99° or occasionally to 100° F. may be observed. A high temperature, if present, is a symptom of either a mixed infection or of general tuberculosis. The kidney is felt enlarged in a small number of cases of uncomplicated renal tuberculosis. Even when it is considerably enlarged it may be adherent high up under the diaphragm and not be felt.

A thickened tuberculous ureter may be detected on deep palpation at the level of the brim of the pelvis in a thin subject, or on rectal examination in the male subject, or on vaginal examination as a thick cord in the lateral fornix. It is a characteristic of renal tuberculosis that the disease may have advanced so far as completely to have destroyed one kidney without causing symptoms that attract the attention of the patient. The symptoms may vary, and in some cases may disappear for considerable periods. In the majority of cases, however, the symptoms are slowly progressive.

In closed renal tuberculosis there is often a history of irritability of the bladder which has subsided some time ago; the urine contains albumin, a trace of pus, or some red cells. The kidney and ureter may be palpable. X-rays show calcification and cystoscopy shows a closed and drawn-out ureter. Under unfavourable circumstances a closed tuberculosis may become active again.

Diagnosis. The development of symptoms of cystitis in a young adult will suggest tuberculous kidney if there is also albuminuria, which is a constant symptom. Pyuria, with a sterile urine, is also strongly suggestive. In 20 per cent. of cases tubercle bacilli are not found by staining or by injection into a guinea-pig. Tuberculous bacilluria occasionally occurs in phthisis without the kidney being itself tuberculous. With the bacilluria there is probably a non-specific tuberculous nephritis (see above); but the presence of tubercle bacilli with pus means renal tuberculosis. In many cases, but not in all, cystoscopic examination gives characteristic appearances; in cases of doubt the ureters should be catheterised; but this cannot be done if the bladder is extensively involved. X-ray of the kidneys gives positive results in 20 per cent. of cases. The shadows are usually more irregular than those of calculi and their density low and uneven; however, a caseous mass yields a uniform heavy shadow, and if the whole kidney is involved, a mosaic of round or oval shadows is obtained.

Prognosis. As already indicated, healing occasionally takes place without operation; statistically, there is a mortality of over 50 per cent. within five years of diagnosis. The immediate mortality of operation is 2 to 3 per cent., and up to 80 per cent. are restored to health.

Treatment. The usual treatment is nephrectomy; the presence of genital tuberculosis is not a contra-indication; but operation should not be carried out if there is active tuberculosis elsewhere in the body, or if both kidneys are affected. In default of this, ultra-violet light, tuberculin and other general measures described under Phthisis may be tried.

HYDRONEPHROSIS

By this term is meant dilatation of the pelvis and/or calyces of the kidney by retained urine. It occurs at all ages, and is more frequent in females than males. It may be congenital or acquired. **Congenital Hydronephrosis** may be in actual existence at the time of birth, when it may be so large as to constitute a serious obstacle to delivery; or it may develop after birth, although it is due to congenital causes; or it may be entirely the result of disease occurring in later life. Among the congenital causes are various abnormalities of the ureter, such as twists upon its axis, folds, reduplications, and valvular arrangements of the mucous membrane, contractions, or conversion into a fibrous cord.

Another cause is an imperforate urethra. Congenital hydronephrosis is often associated with other congenital defects and malformations, such as club-foot, hare-lip, or malformations of the external genitals; and those affected with it are frequently still-born, or live only a short time.

Acquired Hydronephrosis. Apart from congenital hydronephrosis, there are four types of acquired hydronephrosis: (1) *renal*, usually associated with calculus, causing a large kidney, in which the calyces are dilated and there is destruction of the renal parenchyma; (2) *pelvi-renal* due to obstruction below the junction between the pelvis and ureter; the obstruction may be in the lumen, *e.g.* an impacted calculus; in the wall of the ureter, *e.g.* a growth or inflammation; or from pressure outside or in the urethra, including enlarged prostate; (3) *pelvic*, where the pelvis is mainly affected and there is not much dilatation of the kidney. This has been called congenital without much evidence, and undue mobility of the kidney, kinking over the inferior branch of the renal artery going to the hilum, valves and folds at the pelvi-ureteral junction have also been brought forward as explanations, again without much evidence. A more reasonable explanation is that there is in these cases an achalasia of the sphincter at the pelvi-ureteral junction. (4) There is some dilatation of pelvis and ureters when there is a permanent increased flow of urine as in diabetes insipidus.

It has been repeatedly stated that tying the ureter in an animal fails to produce hydronephrosis, but this is not so, and obstruction, of itself, is quite sufficient to account for hydronephrosis in many cases without postulating that such obstruction shall be incomplete or intermittent.

When the calyces dilate, the kidney undergoes the following changes of chronic interstitial (consecutive) nephritis: the colour is pale pink or pale yellow; on section it is found that the pyramids are flattened, while the cortex is relatively broad. Under the microscope there is found infiltration of the organ with leucocytes, chiefly around the Malpighian corpuscles, and in the intertubal tissue; there is also some glomerular change, with a slight alteration of the tubal epithelium. In certain cases the process may go on to contraction of the new tissue, and the production of cicatrices. If the obstruction is lower down—for instance, at the vesical orifice of the ureter—the ureter itself is involved in the distension. Moderate degrees of hydronephrosis with consecutive induration of the kidney are common as the result of carcinoma of the uterus, vagina, and bladder. In extreme cases the pelvis becomes distended, and the kidney more and more flattened out; and finally a large cyst is formed capable of containing 40 or 50 ounces, or even several pints of liquid, and consisting of a thin membranous sac, which may present here and there portions of the kidney substance, but in some cases is quite destitute of any trace of it. Inside the sac there are sometimes septa dividing it into separate cavities. If the ureter is involved, it may be enormously dilated, to the size, perhaps, of the small intestine or colon, or it may be entirely merged in the distended pelvis and kidney. Hydronephrosis may affect one or both kidneys, according to the situation of the lesion or lesions causing it. Some dilatation of the right pelvis is commonly produced in pregnancy by pressure of the uterus on the ureter.

The liquid of a hydronephrosis varies with the amount of kidney substance still remaining; generally it is equivalent to a very dilute urine and there may be a trace of albumin and a little pus; but pus in any quantity is not present unless there has been previous pyelitis, and the condition is then a pyonephrosis.

Symptoms. A moderate degree of distension on one side, when the other kidney is healthy, may cause no symptoms whatever. If it is considerable, then a swelling is formed which becomes the prominent feature of the case, and has the usual characteristics of a renal tumour. It occupies one or other flank, extending from the costal margin to the crest of the ilium, and reaching, according to its size, towards the middle line, or even beyond it. A cyst holding 40 or 50

ounces may cause scarcely any prominence of the abdomen, but its presence will be detected by resistance to deep pressure, and by the difficulty of bringing together the two hands, placed one in front, the other under the last rib. With larger cysts, an unsymmetrical enlargement of the abdomen is produced, and the loin and flank are bulged. Sometimes the cyst is limited to the upper part of the abdomen, and may resemble enlargement of the liver by hydatid. The tumour is smooth or lobulated, in some cases tense, in others quite flaccid; and fluctuation can be sometimes obtained. The colon lies in front of it, and may cause a resonant note.

An important feature of the tumour of hydronephrosis is its liability to diminish in size suddenly, or even to disappear, from the escape of its contents into the bladder. Immediately afterwards the patient has an abundant discharge of urine; and the cyst again slowly fills. Slighter variations in size or tenseness may occur without any corresponding change in the urine being noticed. Local symptoms may be caused by the tenseness of the cyst, or its pressure on surrounding parts, such as pain, vomiting, dyspnoea, or interference with the heart's action. But these may be entirely absent; and pain is severe only when the obstruction is sudden and complete. The urine in hydronephrosis may not be much altered, since the healthy kidney compensates for the deficiency of its fellow. In cases of double hydronephrosis uræmia may occur; the earlier indications of obstruction, when there is no tumour, are pains in the back or abdomen, partial suppression of urine from time to time, and increased frequency of micturition.

Pyonephrosis may be looked on as a hydronephrosis filled with pus; the physical signs are the same, but there is commonly fever like an abscess in any other part of the body and the treatment is surgical.

Diagnosis. The tumour of hydronephrosis has to be distinguished from perinephric abscess, from pyonephrosis, hydatid of the liver or spleen, and, in extreme cases, from ascites and ovarian tumour. The history (*e.g.* of calculus) may be the same in hydronephrosis, *pyonephrosis*, and *perinephric abscess*; the first is generally of longer duration, without severe, or even any, constitutional symptoms, whereas the other two conditions are likely to show evidence of suppuration with fever. Perinephric abscess also gives the local signs of acute inflammation. In the absence of fever, pyonephrosis may not be diagnosed from hydronephrosis, and it may develop from it. *Hydatid* of the liver or spleen presses forwards or upwards, bulging the lower ribs, while hydronephrosis occupies the loin first. *Ovarian* tumour should be recognised by the history of the enlargement, the position of the uterus, and the absence of the colon from the front of the cyst. The spontaneous disappearance of the tumour, coincident with an increased flow of urine, is suggestive of hydronephrosis; but the only certain method of diagnosis is by uroselectan or retrograde pyelography (*see* Plates 39 and 40).

Prognosis. A simple hydronephrosis may cause little or no trouble for many years; the kidney may gradually undergo atrophy without the distension being such as to cause any serious trouble. The risk in such a case is that the other kidney may be at some time involved (*e.g.* by calculous obstruction). If the cyst reaches a great size, or becomes very tense, it may rupture into the peritoneum, or it may press on adjacent parts—the stomach and diaphragm—and cause death by interference with respiration or circulation.

Treatment. The treatment is palliative, but in the end surgical measures will probably be required. Aspiration may be carried out as a temporary measure if the cyst is large, the needle being inserted at the side into an area dull to percussion; a suitable place on the left side is just at the anterior end of the eleventh intercostal space; on the right side, half-way between the last rib and the crest of the ilium, and 2 inches behind the anterior superior spine of the ilium.

NEW GROWTHS IN THE KIDNEY

The following tumours are met with in the kidney : Adenoma, fibroma, forming small round nodules in the pyramids, leukæmic deposit, masses of lymph-adenoma in Hodgkin's disease, cavernous angioma, papilloma, epithelial carcinoma, and embryonic tumours. The fibroma in reality starts as a myoma, and fibrous tissue is deposited as the tumour grows older. Embryonic tumours and carcinoma are, as a rule, the only ones large enough to become of clinical importance. Small accessory suprarenals are also seen in the upper pole of the kidney. They are of no clinical importance.

EMBRYONIC TUMOURS

These are generally primary, and frequently occur in quite young children or infants. The organ is enlarged to an immense size, often filling half the abdomen. It presents the usual characters of a renal tumour, filling out the loin, but increasing downwards and inwards towards the umbilicus, having the colon in front of it, and rounded or oval, with no sharp edges or notches. Histologically the tumour recapitulates the development of the kidney, being composed of tubule cells and stroma containing unstriped muscle fibres. It may contain round cells and spindle cells ; and its consistence varies, sometimes being hard, at others so soft as to invite exploration for fluid. The tumour grows rapidly, causes neither pain nor hæmorrhage, but kills finally by exhaustion and emaciation. It is often bilateral.

EPITHELIAL CARCINOMA

This is primary or secondary. In *secondary* carcinoma the nodules are small, and their presence is not generally productive of special symptoms. As a rule, both kidneys are involved. *Primary* carcinoma occurs mostly in persons of middle or advanced age, and is more frequent in men than in women. There are two main types. (1) In the *pelvis* there is (*a*) the villous papilloma, which tends to be multiple in the ureter and bladder, and (*b*) carcinoma of the pelvis, consisting of squamous or transitional cells. This latter keratinises very quickly, becoming a typical epithelioma. It is found in association with calculi ; and it may be assumed, as in the analogous case of hepatic cancer and biliary calculi, that the calculi have acted as a constant source of irritation. It mostly affects one side only. It causes considerable enlargement of the kidney from hydronephrosis or from blood in the pelvis (hæmatonephrosis) ; but it rarely becomes, proportionately to the body, as large as does sarcoma in children. (2) In the second place, there is the tumour which arises from the substance of the kidney itself. The cells very readily undergo fatty degeneration and hydropic distension, and when this is the case, they are called *Grawitz* tumours, or, from the close resemblance of their elements to those of the fasciculate layer of the suprarenal cortex, have been called *hypernephroma*, and they have been thought to arise from suprarenal remains in the substance of the kidney ; but they present features which are not present in the suprarenal structures, and are more probably epithelial growths from the cells of the convoluted renal tubules. They are often encapsuled, and present on section irregular division into lobules by fibrous tissue, with scattered areas, some of bright yellow colour, others of red or brown colour, in addition to cysts the walls of which may be calcified. The tumour cells vary in size, often reaching the dimensions of giant cells ; and they have a tubular or alveolar arrangement, or are grouped radially round vessels. Clinically these tumours are especially important, as they readily invade the pelvis of the kidney and give rise to hæmaturia. In other cases the carcinoma does not resemble the suprarenal, but has cells of relatively small size with a large nucleus and a protoplasm darkened by numerous granules.

Symptoms. These are tumour, hæmaturia, and pain. The signs of

the *tumour* are similar to those of hydronephrosis (*q.v.*); it is usually smooth but may be nodular; its mobility may be limited to adhesion; manipulation will elicit tenderness. Rarely the tumour pulsates, and a *bruit* may be heard in it. *Hæmaturia* is present in over 90 per cent. of all cases and as an initial symptom in nearly 70 per cent. (22); it is intermittent, variable in amount, and may form thin round clots. Albumin does not occur without blood, unless there is independent nephritis or pyelonephritis and in this case pus cells will be present as well. Carcinoma cells are sometimes recognised, but they may be lost among blood corpuscles; or epithelium from the bladder or pelvis may be mistaken for them: and on the whole they cannot be relied upon for a diagnosis. The urine may be perfectly normal. *Pain* and tenderness are variable and often absent in the early stages. The pain may be an aching in the loin or it shoots down the groin to the thigh, as a colic with passage of the clots (see Renal Calculus). Extension of the growth to the lymphatic glands may lead to pressure upon the roots of the spermatic veins and the production of a *varicocele*; or *œdema of the legs* may occur.

Diagnosis. Carcinoma of the kidney may be recognised by the co-existence of hæmaturia, pain and tumour of the renal region. Painless hæmaturia is most commonly caused by a tumour of the kidney or bladder. A palpable tumour has to be distinguished, first, from enlargements of other organs; secondly, from other diseases of the kidney. The points of distinction between a renal tumour and other organs have been dealt with (see p. 505). If cancer of the *colon* simulate renal cancer, intestinal symptoms are mostly present. *Accumulated feces* on the left side would show more variability in size and consistence, and the diagnosis can be cleared up by the use of an enema.

The diseases of the kidney which may resemble carcinoma are pyonephrosis, hydronephrosis, hydatid, cystic degeneration, and tuberculous disease. From the first three it should be distinguished by its solid feel. A tense uniform globular surface would be in favour of a cyst, but a lobulated hydronephrosis may be mistaken for new growth. By the time that *tuberculous disease* causes enlargement enough to resemble cancer, it is practically a pyonephrosis. *Cystic disease* commonly involves both kidneys, and has not the other local signs of cancer; the pale abundant urine, with a trace of albumin, should distinguish it.

X-rays after uroselectan, cystoscopy and retrograde pyelography should be used in diagnosis. The X-ray appearances are variable; there may be elongation of a calyx with a possible concavity of one aspect facing a rounded tumour or a filling defect of the pelvis in a pelvic tumour.

Treatment. In operable cases the treatment is nephrectomy; ten patients out of thirty-three have survived from under two till twelve years (22).

CYSTS IN THE KIDNEY

The following forms of cystic disease of the kidney occur: (1) Small cysts in granular kidneys already described; (2) extensive cystic change known as *cystic disease* or *polycystic kidney*; (3) simple cysts; (4) dermoid cysts, which are exceedingly rare, and have the same characters as elsewhere; and (5) hydatid cysts, which have been dealt with.

CYSTIC DISEASE

(*Polycystic Kidney*)

This is a congenital disease, and may lead to enormous abdominal distension of the foetus, with serious difficulty in parturition. Less advanced degrees of it are compatible with life, and it may be found at any age. The condition is usually bilateral. In adults the organs weigh from 1 to 5 or 6 lbs. It is more common in males than in females.

Pathology. On section the kidneys are seen to consist almost wholly of

cysts of various sizes, containing a fluid which is clear or turbid, yellow, pink, red, or purple, sometimes viscid, colloid, or purulent. Always albumin, and sometimes blood discs, leucocytes, and cholesterin, are found in the fluid, but urea and uric acid are generally absent. The cysts are surrounded by fibrous tissue, in which only remnants of renal tissue can be found; they are lined with epithelium. The pelvis, ureter, and bladder are healthy, or the pelvis may be dilated. The pathology of these kidneys is still open to doubt. The view of Shattock has been widely accepted that a fault has occurred in the development of the kidneys. The latter are formed from two different sources. The pelvis and collecting tubules arise from an upgrowth of the ureter which comes from the Wolffian duct; the rest of the kidney comes from the "intermediate cell mass," derived from the mesoblast of the coelom. When these two fail to meet each other, the secretion of the kidneys does not escape, and cysts are formed above the junction.

Symptoms. In congenital cystic disease the kidneys may occupy the greater part of the abdomen, and press upon the diaphragm; and death may happen *in utero*, or during birth; or the child may survive a few months, or in the event of the disease being unilateral, a few years, when at length death may result from uræmia. The change is often associated with other congenital malformations, both of the urinary organs and other parts.

In adults the symptoms are often very obscure, but resemble those of secondary contracted kidney (*q.v.*). Sometimes there is hæmaturia. Hypertrophy of the heart and high arterial tension and raised urea in the blood occur in advanced cases. There may be lumbar pain. The kidneys are often large enough to be easily felt. They occupy the usual positions of the kidneys, are rounded, nodular, firm or elastic in different degrees, and descend on inspiration, and one is usually larger than the other. The termination is like that of secondary contracted kidney and the **prognosis** depends on tests of renal function.

Diagnosis. This depends on finding a bilateral swelling of both kidneys of different size, usually without constitutional symptoms but with impairment of renal function. X-rays after uroselectan show that all the calyces are elongated into spidery processes (22).

The **Treatment** is that of secondary contracted kidney.

SIMPLE CYSTS

Cysts of considerable size are sometimes found. They may be 3 or 4 inches in diameter, and exceptionally very much larger. They arise from the cortex, and project on the surface. Their contents are a clear limpid or gelatinous fluid, containing a little albumin and some salts, but no urea or uric acid. The remainder of the kidney may be quite healthy. Such cysts may be unrecognised during life; if very large, they form tumours which may require to be treated surgically on the same principles as hydronephrosis.

MOVABLE KIDNEY

The name *movable kidney* is given to one that is readily displaced from its normal position, and can be moved more or less freely in the abdomen. This unusual mobility may be congenital or acquired.

Congenital mobility is due to the presence of a *mesonephron*—that is, the kidney is partially or completely surrounded by peritoneum (like the colon), and is thus free to move about among the abdominal viscera. This condition is quite rare. It is sometimes distinguished as *floating kidney*.

Acquired mobility is much more common. It affects females more often than males; and the right kidney is movable thirteen or fourteen times as often as the left. Sometimes both are affected at the same time. The age of the patient

is mostly between twenty and fifty. It mainly results from conditions which stretch or relax the tissues and structures surrounding the kidney, especially the fatty capsule and the peritoneum. Perhaps the most frequent cause is repeated pregnancy, by which the peritoneum is dragged upon and stretched, and fails after delivery to recover its normal tension. But movable kidney is not confined to those who have borne children. Emaciation by reducing the fat surrounding the kidney may be a cause sometimes. Many patients have a pendulous abdomen, and the general want of tone in the abdominal and pelvic tissues which constitutes Glénard's disease. An increase of size of the kidney from any cause must favour it. Tight-lacing has been charged with it, but it frequently occurs independently.

Symptoms. At the present day much doubt is thrown on movable kidney itself as being a cause of any symptoms; these are rather considered to be due to an associated pyelitis, hydronephrosis or other associated disease. There is no evidence that movable kidney causes anxiety or hysteria though it may occur in such patients as in perfectly healthy individuals. The symptoms which have been attributed to movable kidney are a sensation of weight, or dragging, or pain in the loin or side of the abdomen affected; and this may be constant, aggravated by walking or exertion, and relieved by lying down. From time to time there may be severe attacks of so-called *strangulation* of the kidney (*Diel's crises*), consisting of great pain and tenderness in the renal region, with scanty high-coloured, and even bloody urine. There may be nausea or vomiting, and malaise, but generally not much pyrexia. Such an attack, which subsides in the course of a week or more, is probably due to twisting or kinking of the renal vessels by the movement of the kidney.

The evidence of movable kidney lies in its detection by palpation. It is felt at the end of inspiration as a smooth, firm, rounded tumour in the loin, of the size of the kidney. The examination should be made with both hands, one pressed firmly in between the last rib and the crest of the ilium, the other on the front of the abdomen. If it lies between the last rib and the crest of the ilium, it can be pushed more or less in all directions, but most easily upwards towards the thorax, when it may get entirely out of reach, leaving the flank normal. The best means of confirming the diagnosis is to X-ray the patient in the vertical position fifteen minutes after injecting uroselectan, immediately after the horizontal film has been taken.

Treatment. From what has been said it is the associated condition, which is probably responsible for the symptoms, that requires treatment rather than the mobility itself. If it is desired to retain the kidney in its normal position an abdominal belt, just as described under Gastropsoxis, is the best appliance rather than any pad applied directly against the kidney itself. A further desideratum is to strengthen the abdominal muscles by suitable gymnastic exercises. The treatment of acute symptoms consists in complete rest, the use of poultices and hot fomentations to the loin and abdomen, and opium or morphia by injection or suppository.

RENAL CALCULUS

(*Nephrolithiasis*)

The following are the varieties of urinary calculi. The first six are the commoner forms; the others are much more rare:

1. *Uric Acid*. Hard, round or oval in shape, smooth or finely tuberculated, sometimes faceted from contact; of yellowish, fawn, or reddish colour. They vary in size, from that of poppy seeds to that of mustard seeds or peas, and are occasionally very much larger. Frequently they exist in great numbers.

2. *Sodium Urate*. Soft, not generally of large size.

3. *Calcium Oxalate, or Mulberry Calculus*. These are very hard, rough or

irregular on the surface, and of blackish-brown colour; when smaller they are smooth, rounded, grey or brown in colour. Generally they are solitary.

4. *Mixed Calcium and Ammonium-magnesium Phosphate, or Fusible Calculus.* The mixed phosphates are precipitated in urine rendered alkaline by ammoniacal decomposition, such as occurs when the secretion is retained in the bladder or in a dilated pelvis. They rarely form the nucleus of a stone, but are deposited upon other calculi of uric acid or oxalate, upon foreign bodies (*e.g.* in the bladder), and upon the inflamed mucous membrane of the bladder or of the renal pelvis. They may thus enormously increase the size of vesical stones, and in the pelvis may form concretions, which are moulded to all the infundibula and calices (*dendritic calculi*). The deposit is white, soft, and friable; and fuses under the blowpipe into a kind of enamel.

5. *Calcium Phosphate.* White and chalky, rather smooth on the surface, with an earthy fracture, varying in size from that of a pea to that of a hen's egg.

6. *Mixed.* Phosphate-oxalate, urate-phosphate, urate-oxalate, urate-oxalate-phosphate; these account for 86 per cent. of all stones, and each of the two latter for over 30 per cent. (23) in India, most of them being found in the bladder.

7. *Calcium Carbonate.* Small, very hard, smooth, grey, yellowish or bronze-coloured, and varying from minute grains up to stones the size of a hazel nut; these are common in cattle.

8. *Cystine.* Usually egg-shaped, the surface granular, glistening with crystals of yellow colour, looking translucent on section with indications of a radiating structure, and rather soft in consistence. They become green on exposure. With a lens the hexagonal form of the crystals may be seen.

9. *Xanthine.* In physical characters like uric acid calculi, but of a cinnamon colour, soluble in liquor ammoniæ and liquor potassæ. They are extremely rare, and have not been found in the renal pelvis.

10. *Urostealith.* Soft, greasy concretions, which have been found in a few cases; one was shown to consist of about one-third cholesterin and fat, one-third uric acid, and some oxalates.

11. *Indigo.* Once found in the renal pelvis by Ord as a calculus weighing 40 grains.

Urinary calculi vary much in size; they may be 2 or 3 inches in diameter, or they may consist of very small particles, and are then known as *gravel*.

The centre or nucleus (*i.e.* the first-formed portion) of most calculi is uric acid; but within that, calcium oxalate or sodium urate has been found. Some calculi are deposited upon a nucleus of blood clot, mucus, or renal casts, and the ova of *Schistosomum hæmatobium* may form the starting-point of renal stones. Most calculi are formed in the urinary tubules, and some even in the epithelial cells (Ralfe); the cell substance acts as "colloid" around which the calculus grows by accretion of other deposits upon it, for there is evidence that in some cases renal calculi may begin in a cyst in the cortex and be discharged into the pelvis (36). The effect of the reaction of the urine in precipitating phosphates and urates has been dealt with on p. 507, and further growth of renal calculi probably takes place after they have been discharged into the renal pelvis.

Ætiology. Calculus is very much more frequent in the eastern part of England than in the middle or western parts; and in India in Sind, the N.W. Frontier Province and the Punjab. It is more common in males than in females. Experimental evidence suggests that a number of factors are responsible—dietetic, especially whole wheat flour, oatmeal; lack of vitamin A, causing epithelial desquamation in the urinary tract; physico-chemical, a deficiency of phosphates relative to calcium in the diet; infection, the streptococci cultivated from nephrolithiasis have an *elective localisation* (*see* p. 347) for the urinary tract (23).

Symptoms. (1) When the stone exists in the pelvis of the kidney, it may be entirely latent, or it may give rise to the symptoms described below, which

apply to the presence of a stone either in the pelvis or ureter, or to the passage of pus from an associated pyelitis ; and these symptoms may result from the presence of very small stones or gravel. (2) If it falls into the ureter, it may become impacted or move along with great difficulty, causing *renal colic*, hæmaturia, and, in certain circumstances, *obstructive suppression*. (3) The later effects of renal stones, either in the kidney, or after impaction in the ureter, are pyelitis of all degrees, pyelonephritis, perinephritis, perinephric abscess, hydronephrosis and pyonephrosis, the symptoms of which have already been described.

Gravel and calculus are frequent causes of *lumbar pain*, which is often regarded as "lumbago" or muscular rheumatism. The lumbar pain or aching may be rendering worse by jolting or shaking. Aching pains may also be felt in the iliac fossæ above the pubes and in the penis ; they may be brought on by micturition, being felt during or after the act. There may be frequency of micturition. If the symptoms are of long duration, albumin, pus, or mucus may be passed, and from time to time blood in varying quantities. Occasionally, small calculi or gravel are discharged with the urine.

Renal colic is due to a sustained contraction of the muscular fibres of the ureter, and it may be due to irritation by the calculus in the pelvis or by its impaction in or passage down the ureter. It is comparable with biliary colic, and is characterised by intense pains, rigors, nausea, and vomiting. The pain is situated in the loin and flank of the same side, and radiates downwards and inwards to the groin and testicle ; sometimes to the thighs, and even to the heel and sole of the foot ; at others to the abdomen, chest and back. In the severer attacks the patient is doubled up with the pain, or writhes on the floor, and bursts out into profuse perspiration, or he becomes pale and collapsed, with quick, feeble pulse ; but the temperature may be raised. With this there are nausea and vomiting, often a rigor, and sometimes even general convulsions. The testicle on the same side is retracted, and is swollen and very tender. The pain may be less for a time, but soon returns, and altogether it may last a few hours or a day or two, until at length the stone is passed into the bladder, or returns to the pelvis, when there is a sudden relief, and only an aching, smarting sensation in the side is left. The pain may, however, cease when the calculus still remains impacted in the ureter. During the attack, micturition is frequent and painful, and the urine is scanty, coming, perhaps, only by drops ; and it may contain blood. By examination of the abdomen the kidney may be found to be tender and the muscles somewhat rigid, but not nearly so rigid as in peritonitis. A stone in the lower ureter may sometimes be detected on rectal examination ; or the stone may be detected in the ureter, and its course watched from kidney to bladder.

Such an attack may occur spontaneously, or may be brought on by some movement which appears to dislodge the calculus from its position. Renal colic may recur in the same patient. This, of course, must depend on the number and size of the stones ; obviously, if a stone gets back into the pelvis it may set up renal colic on again becoming impacted. Exceptionally a large number of stones in the pelvis of the kidney may be detected by a crackling sensation on palpation. The subsidence of symptoms entirely after a long period of activity may be due to the calculus becoming encysted.

Obstructive suppression is distinguished from the suppression which results from acute congestion or acute Bright's disease, and the symptoms in marked cases are strikingly different. It arises when both ureters are simultaneously compressed, as occurs in women when cancer of the pelvic organs invades the base of the bladder ; or when one kidney has been disorganised, or excised, or otherwise placed *hors de combat*, and a calculus becomes impacted in the ureter of the healthy organ. This condition is sometimes called *latent uræmia*. In some cases no urine is voided ; in others, a certain amount may be passed in small quantities at long intervals, but it is clear, watery, of very low specific gravity—e.g. 1,006—and contains an extremely small quantity of urea or other

solids: and there is no albumin, unless there is blood, or unless the urine is modified by the cystitis which accompanies cancer of the bladder. The patient's condition is not at first materially altered. He may eat as usual, but he loses muscular power, and becomes sleepless, and after some five or six days he is seized with the muscular twitchings or jerkings of *chronic uræmia*, associated with breathlessness and eventually coma, as already described (*see* p. 530). Death, as a rule, ensues from nine to eleven days after the commencement of obstruction, and is very rarely postponed beyond this. Recovery may take place if the obstruction is removed by the passage of the calculus or by the breaking down of any new growth.

Diagnosis. The typical symptoms—lumbar pain, hæmaturia, and albuminuria—may be caused not only by a medium-sized calculus, but also by fine gravel and uric acid crystals, which will readily pass the ureter; and in these cases testicular pain and frequency of micturition may also be present. A severe attack of colic, associated with hæmaturia and testicular pain and retraction, is very strong evidence of calculus; but they may be due to carcinoma, tuberculosis and pyelonephritis.

In carcinoma of the kidney hæmorrhage is often more abundant, and more continuous. Gelatinous red lumps appear in the urine after the blood; and sometimes cancer cells may be found by the microscope. The discovery in due time of a tumour will help the diagnosis. Calculus is more likely in a young patient, but either may be present in middle or old age. *Tubercle* of the kidney may closely simulate calculus, by lumbar pain, frequent micturition, pus in the urine, and even blood. In the former there may be a family or personal history, or present indications of tubercle; hæmaturia and renal pain are less prominent and characteristic. Pyelonephritis is simulated by the frequency of micturition which occurs in renal calculus, especially if hæmaturia is absent. Previous attacks of lumbar pain, and the acid reaction of the urine, if pus is present, are in favour of a renal origin.

X-rays are always now used in the diagnosis of renal and ureteric calculus (*see* Plate 41). However, uric acid calculi are not opaque to X-rays. The shadow of a stone must be distinguished from (1) elongated phleboliths, which may be multiple and run in the line of a vein and not the ureter; and (2) calcified glands which tend to occur in groups. Difficulties in diagnosis may be cleared up by means of uroselectan or pyelography, which will show up the line of the ureter; also the stone may be touched by the catheter. If the bladder be examined with the cystoscope, signs of irritation of the mucous membrane about the orifice of one or other ureter may be observed, and the urine flowing from either orifice may come too slowly, or may contain blood or pus cells (*see also* Examination of Kidney and Bladder). Lastly, an exploratory incision over the kidney or ureter is justified in some cases.

It appears to be quite clear not only that a calculus may cause pain in the opposite flank at the same time as pain on its own side, but also that in exceptional cases the pain has been felt only on the side of the healthy kidney. Stone in the kidney may also cause suprapubic pain, and simulate stone in the bladder very closely. These pains must be set up reflexly, and they show how closely the nervous connections of all parts of the urinary tract are related to one another. Though there are many exceptions to this rule, the symptoms of a calculus in the lower ureter tend to be those which arise from irritation of the lower urinary tract.

Treatment. Gravel, when it is uric acid, should be met by ordering a low purine diet (*see* Gout) and by giving drugs to render the urine less acid. The most efficient are the citrate, acetate, and bicarbonate of potassium or sodium, which may be given in 30 to 60-grain doses in 3 or 4 ounces of water two or three times daily, or in one larger dose before the night's rest, during which time the tendency to uric acid precipitation is greatest. The reaction of the urine should be examined when passed on waking, at 10–11 a.m. when the alkaline tide is about

at its maximum, at night before dinner and before going to bed. A pH between 6 and 7 should be aimed at (*see* Reaction of Urine). On the other hand the urine may be sufficiently alkaline to cause phosphate gravel or phosphaturia, with a pH 6.8 and over; this may be due to a low-protein diet with excess of vegetables and fruit. Apart from increasing the protein, which, of course, also increases the phosphate excretion, the reaction is made more acid by giving ammonium chloride or calcium chloride (*see* Treatment of Pyelonephritis).

If a calculus has actually formed it cannot be dissolved by any medical treatment, but if small it may be passed by increasing the fluid intake. If not, *nephrolithotomy* should be performed, or *nephrectomy* if the kidney is hopelessly damaged, though the power of an apparently hopelessly damaged kidney to recover some function has recently been emphasised, so that nephrotomy is usually to be preferred to nephrectomy, especially as a stone may develop in the other kidney.

Treatment of Renal Colic. Anodynes are here required, both to relieve the intense pain, and because they may also relax the spasm of the ureter, and so facilitate the escape of the stone. If the pain is severe, a morphia injection should be at once given; or morphia or opium may be given internally, or in suppositories, or chloroform or ether may be inhaled. Papaverine hydrochloride, one of the opium alkaloids, in doses of $\frac{1}{8}$ to $1\frac{1}{2}$ grains, has produced good results. Locally, hot poultices, hot fomentations, belladonna applications, or the hot bath should be used. The patient should be at rest, and warm diluent drinks, barley water, etc., should be taken from time to time.

FUNCTIONAL ALBUMINURIA

It has been already shown that albuminuria may occur in a number of morbid conditions, of which nephritis and renal degenerations, acute illnesses, infective diseases, and venous congestion are the most important. But it is sometimes present in persons who appear to be in perfect health, and show no sign of disease on further examination.

Macleod examined the urines of 50,000 soldiers and found albuminuria in 5.62 per cent. of them. In 2.55 per cent. the albuminuria was well marked. Many of these cases were probably examples of functional albuminuria. Numerous observations have also been made on the presence of albumin in the urine in groups of individuals, such as infants from one to six days old, schoolboys, bank clerks, soldiers, or workers in factories; and invariably albumin is found in a certain percentage, which varies from 5 to 30. In life insurance practice it is common experience that a large proportion of applicants between eighteen and thirty years of age, believing themselves to be perfectly well, have a small quantity of albumin in the urine. Many of these cases, no doubt, are examples of functional albuminuria; but others are the result of a previous nephritis, which leaves a "leaky kidney."

Pathology. The albumin is, as a rule, small in quantity, and there is in some cases a high percentage of globulin. Serum globulin consists of euglobulin and pseudo-globulin, and it is the euglobulin fraction that is present in the urine. This substance is often combined with lecithin and other lipid substances, and occasionally the urine becomes opalescent when they are present in large amount. In the albuminuria of nephritis there is six times as much albumin as globulin, but in these cases the amounts are often, but not always, about equal. Euglobulin may be discovered by adding 33 per cent. acetic, drop by drop, to urine until a white precipitate is formed.

The following types, mostly in young people, require separate description.

Athletic Albuminuria. Albumin in small, decided, or even considerable amount is sometimes found in the urine of those who have recently rowed or run

a race, or have undergone other excessive physical exercise. There is no doubt that the albuminuria is only a temporary disturbance, indicative of deficient blood supply to the kidney, because so much blood is required for the muscles and skin.

Dietetic Albuminuria. This is due to the ingestion of large quantities of protein food. In a six months' experiment a man took 337 grams protein daily; the albuminuria gradually increased up to 2-4 milligrammes hourly and casts appeared, at first hyaline, later granular; there were no subjective disturbances or rise of blood pressure. Evidently there was renal damage; but this was temporary, as all these signs disappeared ten days after recommencing a normal diet (32).

Orthostatic Albuminuria. This includes the cases described as postural albuminuria, and probably also the cyclical, remittent, and intermittent forms. It occurs in persons in good health, more often youths or young adults; and it is characterised by the presence of albumin at certain times of the day, while it is absent at others. Thus, in the early morning it cannot be detected; it is present from about 9 a.m. to 5 or 6 p.m., and again disappears from the urine passed at night. The albuminuria is obviously determined chiefly by the assumption of the erect position, and by the accompanying exercise during the day; and it disappears as a result of the recumbent position at night. The amount of food taken has no influence upon it. Sonne has shown that in these cases the important factor is the presence of lordosis, which occurs naturally in the erect position. The left renal vein is compressed between the spine and the aorta. The albuminuria is caused by the circulatory disturbance. The condition is relieved when the patient is lying down. In ten cases of this kind, by catheterising the ureters he showed that it is only the left kidney which gives rise to albuminuria. This condition has been classed as *lordotic albuminuria*. The albuminuria of pregnancy may be partly a left-sided lordotic albuminuria (33).

Paroxysmal Albuminuria. This may undoubtedly occur as a phase of paroxysmal hæmoglobinuria, in which the hæmoglobin breaks up into hæmatin and globulin (*see p. 444*). The patients have malaise, a sallow tint, and subsequently albuminuria; the urine contains at the same time excess of urea and of urobilin.

Diagnosis. The diagnosis may be very difficult, since it has been shown that slight albuminuria resulting from nephritis is often postural and the relative amounts of albumin and globulin are very variable (35). The history of previous nephritis or infection, the condition of the patient—whether he is languid or out of sorts—or impaired function of the kidneys, will be in favour of Bright's disease as the cause, though even then the prognosis will not necessarily be bad. The presence of euglobulin and the complete absence of albuminuria during the night will be in favour of functional albuminuria.

Prognosis. The future of these cases is on the whole favourable, and in the large majority the albuminuria entirely disappears, though it may persist for two or three, or even seven or ten years.

Treatment. Except in the dietetic form, no treatment is required. In this case the protein in the food should be diminished.

DISEASES INVOLVING BONES, JOINTS AND FASCIÆ

THE RHEUMATIC DISEASES

THE derivation of the word rheumatism has already been given (*see* p. 257), and the diseases in Group A of the Ministry of Health's classification, viz. rheumatic fever, subacute rheumatism and rheumatic purpura, have been dealt with elsewhere. Group B comprises "non-articular manifestations" such as fibrositic or muscular rheumatism, and includes lumbago, sciatica and brachial neuritis. Group C comprises joint diseases, viz. rheumatoid arthritis, osteoarthritis, including "senile hip disease," acute and chronic gout, and unclassifiable chronic joint changes.

The importance of the rheumatic diseases is seen from the following statistics (4). Out of 1,000 insured men and 1,000 insured women over sixteen, during each year 930 would seek medical advice for all kinds of affections, and 55 of these would complain of rheumatic disease, made up as follows: A. Acute rheumatism—4 men, 5 women. B. Fibrositis—19 men, 11 women. C. Arthritis—8 men, 6 women. It must be remembered that insured women, owing to marriage, are on the average younger than the men. Of the trades it is the metal workers who suffer most and especially the puddlers among the steel workers, probably because they have alternate periods of very strenuous exercise and of sitting to cool in a draught. In general the incidence increases with age.

It will be convenient to deal here briefly with *infective arthritis*, a miscellaneous group of diseases, in order to exclude them from the rheumatic diseases proper.

Infective Arthritis. Apart from rheumatic fever it will have been observed that in several of the infectious diseases arthritis has been mentioned as a complication, such as typhus, scarlatina, small-pox, typhoid, influenza, dengue, pneumonia (pneumococcal arthritis), streptococcal and staphylococcal septicæmia, gonorrhœa, bacillary dysentery, syphilis, both congenital and acquired, and tubercle. Infective arthritis in these diseases may be a simple synovitis, which soon recovers; or it may result in ankylosis, as in tubercle; or in suppuration, as in invasion by pyogenic organisms. The symptoms are pain and tenderness, with or without swelling of the joints, and it may be only in the history and associations of this arthritis that means of recognising its origin can be found. The fact that salicylates give relief to the pain and lower the temperature is not evidence that the disease is specifically rheumatic fever. The milder forms subside with rest, severer forms require splints and fixation, and where suppuration is recognised the joint should be opened and drained, or the pus may be aspirated, and flavine, 1 in 1,000, injected. Passive movements should be carried out as soon as the acute stage of the inflammation has subsided, so as to prevent fixation.

FIBROSITIS

(*Myalgia, Muscular Rheumatism*)

This name is given to a painful affection of the muscles or fasciæ which depends upon local changes of an inflammatory nature. The incidence is greatest in winter and at a minimum in summer.

The pain is probably caused by swelling of the interstitial connective tissue in the muscles, their tendons and their fascial attachments, which results in compression of the nerve endings. The swelling is due to exudate either as the result of poisons (bacterial or chemical) deposited from the blood stream or of tearing of the tissues through strain or injury.

In one group of cases then the cause of fibrositis is to be found in some source of toxæmia, such as a septic focus or disorder of metabolism allied to gout. Fibrositis is often associated with osteoarthritis. In these cases exposure to cold appears to be an important factor in causing the local deposition. In the second group a history of muscular strain is to be obtained. No absolute distinction can be made between these two groups, since local injury may provide a nidus for the action of toxins.

Symptoms. As a rule only one muscle or tendon is affected, and the pain at the beginning is localised to a single spot. It is experienced whenever the part involved is stretched or pulled upon either by contraction of the muscle directly affected or of its antagonists. Pressure at the site of the disease will also produce pain. If, on the other hand, the patient can be induced to relax his muscles completely, passive movements gently performed are painless, this point serving to distinguish the condition from arthritis of the neighbouring joints. The onset is usually acute, with sharp pain experienced on movement.

A common situation is in the lumbar muscles, when it is often called *lumbago*. Movements such as stooping become exceedingly painful, and walking is only accomplished with a stiff back. Sometimes, after an interval of three or four days, pain is felt in the buttock and sciatica develops, this being presumably due to an extension of the inflammation to the sciatic nerve sheath. If this happens the sciatica overshadows and outlasts the original lumbago. The muscles of the shoulder girdle are often affected, especially the attachments to the humerus of deltoid and pectoralis major. In this case movements of abduction and adduction give rise to pain, and the arm is held to the side in walking, being sometimes supported at the elbow by the other hand to relieve tension in the affected muscles. Here again the inflammation may spread to the nerve sheaths of the brachial plexus, with resultant brachial neuritis.

The muscles of the neck are sometimes attacked, the condition being then commonly known as *stiff neck*. This is particularly apt to occur from exposure to cold, such as results from sitting in a draught.

More rarely one of the intercostal muscles is involved, so that breathing and coughing cause pain. The condition is then known as *pleurodynia*, and simulates pleurisy, but there is no rub, and constitutional disturbance is slight or absent.

Occasionally the muscles of the scalp are affected, when the acts of wrinkling the forehead and mastication are painful.

Myositis ossificans is a disease in which the muscles are converted into osseous tissue. It always begins in early childhood, invades first the muscles of the back, and runs a progressive course. Bony deposits arise also from injury, most commonly in the extensor cruris, and in the brachialis anticus (*traumatic myositis ossificans*). It gives a characteristic radiogram and may be allied to osteoarthritis.

Diagnosis. This depends upon the presence of definite muscular tenderness on deep palpation, and pain which is constantly brought on when the involved group of muscles is put upon the stretch. Here also, as in the case of neuritis, it is most important to be on the look-out for signs of underlying disease of the nerve roots or the viscera, the pain from which is referred to a peripheral distribution, and may, especially in the case of visceral disease, give rise to muscular tenderness and rigidity. The lightning pains which occur in the early stages of tabes are very often erroneously put down to muscular rheumatism. A myositis occurs in various infectious diseases (*infective myositis*), producing a diffuse swelling and infiltration of the muscle, or abscesses may form, as seen in pyæmia (*metastatic*

myositis), septicæmia, glanders, typhoid fever, and malignant endocarditis. Trichiniasis, already described, is essentially a parasitic myositis. Finally, there is a rare form of polymyositis, which is a type of acute rheumatism.

Prognosis. The course of the illness, provided that it is properly treated and is uncomplicated by neuritis, is usually brief. When, however, proper rest cannot be obtained, the pain may persist for many weeks. Complete recovery is the rule, but recurrences are common, especially in the cases of traumatic origin.

Treatment. If septic foci are considered to be the cause of the trouble, these should be eliminated. The bowels should be well opened, *e.g.*, by drinking a pint of saline water on waking, as described under Raynaud's disease. Muscular exercise should be regular but not excessive. Precautions should be taken against undue exposure to cold and wet. Aspirin and phenacetin should be given for the relief of pain, and a mixture containing 10 grains of sod. sal. or 5 grains of pot. iod. In some cases, especially when fibrositis is associated with evidence of gout, atophan is useful. A purine-free and low-protein diet may be valuable. In a mild case in which the pain and tenderness are localised and superficial, vigorous deep massage at the point of maximum tenderness will sometimes bring about a rapid improvement, this result being presumably obtained by the breaking down of adhesions. If, after two or three applications, this method of treatment is not successful it should be discontinued. Heat locally applied by radiation from an electric lamp, and diathermy are useful. A further remedy, for which good results are claimed, is the injection into the muscle or the site of the pain of a solution of quinine and urea hydrochloride, such as is used in local anæsthesia. At the outset of a severe attack diaphoresis is of value and may be prescribed in the form of a Turkish or vapour bath. Once the affection has developed, rest of the inflamed tissues is necessary.

RHEUMATOID ARTHRITIS AND OSTEOARTHRITIS

Ætiology. *Rheumatoid arthritis* is also known as the "proliferative" or "atrophic" type, and *osteoarthritis* as the "degenerative" or "hypertrophic type" of chronic rheumatic arthritis. The morbid anatomy of these two conditions is distinct, but it is quite common for osteoarthritic changes to be grafted on a primary rheumatoid arthritis.

Rheumatoid arthritis occurs at all ages, and in all conditions of life: but it is much more common in women than in men, and there is a strong hereditary factor. Cold and damp certainly often dispose to its occurrence or excite fresh attacks. It is less common in warm climates. Traumatism in the form of continued pressures, or constant strain, also predisposes to the disease. *Osteoarthritis* is essentially a disease of the latter part of life, and the sex incidence is more equal, though it is also commoner in women. The predisposing causes are similar to those of rheumatoid arthritis, and trauma is especially important in the non-articular cases.

Morbid Anatomy. *Rheumatoid Arthritis.* The earliest changes are of a proliferative nature, commencing either in the synovial membrane near the articular margins or in the subarticular layer of cancellous tissue, or in both places simultaneously. The articular cartilage is invaded on its surface after preliminary degeneration by an advancing tide of vascular connective tissue (pannus) derived from the edge of the synovial membrane. The articular cartilage is simultaneously invaded on its deep surface by inroads of vascular connective tissue from the underlying bone. The layers of pannus on two opposed articular surfaces may adhere (fibrous ankylosis), and may even ossify (osseous ankylosis). Increased permeability to X-rays of the epiphyseal region is an early feature and is probably due to absorption of calcium salts. Later, the increased permeability to X-rays is increased by actual absorption of osseous

trabeculae and their replacement by fat, hence the name "atrophic" sometimes applied to this type. The changes in the synovial membrane are also proliferative with enlargement and multiplication of the synovial villi. Histologically there is evidence of chronic or subacute inflammation in the form of rounded foci of small-celled infiltration. Serous effusion may occur into the joints or the capsule may be infiltrated, causing a spindle-shaped appearance. Similar changes may occur in peri-articular bursae or tendon sheaths. In the later stages, lipping of the articular margins and eburnation of the joint surfaces may occur, *i.e.* secondary osteoarthritis (15).

Osteoarthritis. The first change consists in a degeneration of the central area of the articular cartilage. The changes that follow are in a sense all consequent upon this primary degeneration, although they themselves are more inflammatory than degenerative. For instance, the lateral part of the cartilage proliferates and osteophytes are formed to extend the articular area. The subchondral layer of bone becomes sclerosed, hardened and eburnated in an endeavour to form a new joint surface and thus compensate for the loss of the central portions of the cartilage. The changes in the synovial membrane are at first insignificant. There is villous hypertrophy and increased vascularity of the synovial fringes near the articular margins. Later, however, the synovial membrane and capsule become thickened and fibrous and arteriosclerotic changes may then be seen therein. The histological changes in the synovial membrane and capsule are of the nature of an inflammatory hyperplasia and small-cell infiltration is usually absent. These changes are frequently seen post-mortem in the joints of elderly persons, and are also the result of trauma or long-continued intra-articular irritation. "Loose bodies" in the joint cavities consist in the breaking away of synovial fringes, or of bony osteophytes or nodules of cartilage, so-called epiarticular or periarticular ecchondroses, which occur respectively either in the middle or at the edge of the articular cartilage. It has been claimed, from X-ray evidence, that the characteristic primary lesion is a cyst in the bone itself, surrounded by a densely calcified area, while in long-standing cases multiple cysts are seen (*see* Plate 43, A).

Pathology. There are two factors that will influence the type of rheumatic arthritis produced. Rest tends to cause atrophy of bone, and cutting off the blood supply causes hypertrophy, which is compatible with osteoarthritis, as the disease of arterial degeneration and old age; in this connection it is to be noted that arthritis occurs in pulmonary osteoarthropathy, where the peripheral circulation may be sluggish. But at any rate in rheumatoid arthritis there is often infection from some primary focus elsewhere in the body, and between 60 and 70 per cent. streptococci, mostly hæmolytic, have been isolated from the blood stream and joints, while the blood serum gave positive agglutination and precipitin reactions; negative results were obtained in control cases (16, 17). This work requires confirmation. In many cases the primary foci are in the teeth, consisting of apical abscesses or pyorrhœa alveolaris (*see* p. 321). Less commonly the tonsils are at fault. Other possible causes are adenoids, suppuration in the nasal sinuses or middle ear, uterus, male urethra, urinary tract, open wounds, and the colon, the latter if there is derangement of function. Most cases are probably of streptococcal origin, but the *staphylococcus* and *gonococcus* may also possibly be concerned, and perhaps others, such as *B. coli*. There is also possibly a tuberculous form, described by Poncet. Rheumatoid arthritis is at any rate very closely allied to acute rheumatism, since subcutaneous nodes of the same characteristic histological structure occur in both.

However, focal sepsis is certainly not the whole story, because it exists in many people who are not troubled with chronic rheumatism at all, and its eradication is often not really curative. There is also the problem of the "soil" to be considered, *i.e.* the condition in the individual that renders him liable to this disease. Certainly the disease when contracted is associated with certain

biochemical changes. Microscopic examination of the capillaries of the nail bed shows that the peripheral circulation is defective, so that in the tissues less oxygen is removed from the blood (3); the sugar tolerance curve tends to resemble that found in diabetes (9). Chronic rheumatic arthritis commonly improves during pregnancy, possibly because the respiratory metabolism is itself increased.

The onset of the synovitis in rheumatoid arthritis, as in acute rheumatism, may be an allergic phenomenon, due to some foreign proteins, just like the arthritis of "serum disease," which may follow the injection of antitoxic serum. There is a group of cases called *intermittent hydrarthrosis*, which is certainly of this nature, since it not only recurs periodically, but is often accompanied by or alternates with other well-known allergic symptoms; the disease is rather commonly associated with psoriasis. The synovitis that occurs in hæmophilia may, perhaps, be partly allergic, but also due to the actual effusion of blood in the joint. Finally, the severe muscular wasting of rheumatoid arthritis is accompanied by paræsthesiæ and atrophy of the skin, and is also remarkably symmetrical—points which favour a nervous factor in the disease, and this is of course very obvious in the multiple arthritis of locomotor ataxy and syringomyelia (*Charcot's disease*, see later).

Symptoms. *Rheumatoid Arthritis.* In a minority of cases, especially in young women, the disease is acute and polyarticular; it begins with fusiform swelling of the proximal interphalangeal joints of both hands symmetrically, with pain and tenderness; and subsequently the metacarpo-phalangeal joints, wrists, elbows, shoulders, and joints of the lower extremities are involved, as well as those of the spine, jaw, and the sterno-clavicular joints. There is slight febrile reaction with quick pulse for some weeks; and when this subsides the joints are still limited in their movements, and relapses of fever and swelling of the joints may occur. At the same time the patient becomes anæmic, sweats profusely, and shows pigmentation. There may be subcutaneous nodes and enlargement of lymphatic glands and the spleen. There is depression of spirits and loss of appetite. With each relapse the movements become more restricted, and, finally, ankylosis may result (see Plate 42, A). In a few cases there is carditis as in rheumatic fever. In most cases the disease runs a chronic course throughout.

Very characteristic deformities take place in consequence of the joint changes and the muscular atrophy which is associated with them. Thus the fingers, instead of remaining in line with the metacarpal bones, deviate to the ulnar side, and the joint at the base of the index finger is often greatly swollen; the metacarpo-phalangeal joints are commonly flexed, the first phalangeal joints are over-extended, and the second are flexed; there may be dislocation, especially at the interphalangeal joints, causing quite short, flaccid fingers which are not ankylosed (see Plate 42, D). The lower ends of the radius and ulna project at the back of the wrist. The muscles commonly observed to be atrophied are the interossei in the hand, the muscles at the lower end of the femur, and the deltoid over the shoulder joint. The skin over the affected parts becomes smooth and atrophic. The nerves also in connection with the joints are affected by chronic neuritis, causing pains in the limbs.

A similar clinical picture occurs in children before the second dentition; the arthritis observed in the knees and wrists is often associated with enlargement of the lymphatic glands and spleen, anæmia, sweating, varying pyrexia, and arrest of the bodily development (*Still's disease*). In older persons the disease may also occur with a somewhat rapid onset and affect many joints; or the disease may be more chronic from the commencement. The stiffness is often most marked in the morning, so that movements are at first painful; yet if they be persevered in, the pain will gradually wear off. Sometimes effusion can be readily recognised, and the joint is tense and elastic. In mild cases, which are very common, just one or two joints may be picked out alone.

Osteoarthritis. The onset is insidious, with pain, stiffness and creaking or crepitus on movement of one or more of the large joints ; the disease is commonly non-articular and non-symmetrical, though disease which has as yet produced no symptoms is rather commonly found in other joints if they are examined clinically and radiologically. As time goes on the movements become more and more limited. The general health and nutrition of the patient is unimpaired ; there is no pyrexia except very occasionally during an exacerbation.

There are certain well-defined varieties of osteoarthritis. Disease of the hip (Plate 43) (*malum coxae senilis*) is much commoner in men. The pain and stiffness are followed by very limited movement, eversion and apparent shortening of the limb, and flattening of the buttock. The knee-joint is most commonly affected in women, and this may be partly attributed to the trauma consequent on the increased body weight often associated with the menopause. *Herberden's nodes*, the small nodules or knobs which may form at the sides of the terminal phalanges, are bony outgrowths, and are characteristic of the early stage of osteoarthritis.

Spondylitis deformans, type *ankylopoietica*, occurs ten times as commonly in men as women, mostly between twenty and forty, and is essentially a bony ankylosis of the vertebræ. There may be kyphosis (Bechterew) with compensatory hyper-extension of the cervical vertebræ so as to keep the head erect, and lipping of the anterior edge of the vertebræ owing to pressure, or the spine may remain erect (spondylose rhizomelique of Marie and Strümpell). The bones may show osteoporosis with softening and fragility. The condition is allied to rheumatoid arthritis, though the sex incidence is so different. The back is stiff, and there is tenderness on pressure and percussion over the spine, due to the inflammation, and sometimes the ribs are immovable, so that breathing is entirely diaphragmatic. The rate of progress of the disease varies widely. In some cases the onset is acute and the progress rapid, so that the whole spine becomes rigid within a few months. In others the rate is much slower, and may be arrested when only a portion of the spine has been affected. Sometimes the onset is so insidious that the patient does not seek advice until there is extensive damage. The earliest symptoms are commonly those of lumbago and sciatica, and may be of no great severity. It is not uncommon to meet with a history of such symptoms followed by remission and recurrence after a few months, this happening two or three times before the nature of the disease is recognised. The small joints of the limbs are not often affected. *Spondylitis-osteoarthritis*, sometimes called spondylosis deformans, is osteoarthritis of the spine ; it occurs almost entirely in males mostly between fifty and sixty, and is the result of heavy labour, especially coal-mining ; trauma may be a factor. Pain is not marked unless the exostoses press on emerging nerve trunks. The sedimentation rate is normal, in contrast to the type *ankylopoietica* where it is increased (5).

Diagnosis. In chronic *gout* the articular changes may closely resemble those of rheumatoid arthritis ; in fact, in some cases indistinguishable from rheumatoid arthritis the blood uric acid is quite high and the old term of "rheumatic gout" might be applied here. In the acute cases other forms of acute or subacute polyarthritis must not be forgotten, such as congenital syphilitic arthritis and gonococcal arthritis ; the localisation is often different, and the history will help. Rarely, repeated attacks of acute rheumatism produce permanent changes in the joints. Arthritis affecting one joint only may be confounded with tuberculosis ; but the radiograms of osteoarthritis and tuberculosis are quite different (as seen in Plate 43, p. 559). Disease of the *hip* in elderly people must be distinguished from sciatica and lumbago. This is not easy in the early stage of the disease. Reliance should be placed on (1) local pain and tenderness on pressure over the joint, and pain on movement ; (2) referred pain simultaneously along the sciatic and anterior crural and obturator nerves, since these nerves all supply branches to the joint ;

(3) limitation of movement ; (4) X-ray appearance. Charcot's disease is easily distinguished, and in addition there are nervous signs of *tabes* or *syringomyelia*.

Prognosis. No cure is possible when permanent changes in the joints have occurred, but in the very early stages a cure is possible. However, even in the later stages of the disease very great improvement takes place with careful treatment. In the acute form it is remarkable how altered in outward appearance the joint may be, and yet there may be complete recovery ; but it takes a long time.

Prevention. Care must be taken to prevent the occurrence of septic foci. In particular the teeth must be attended to with regularity.

Treatment. The first step is to see if there is a possible primary focus. It is impossible to exclude the teeth and gums as sources of infection after a superficial examination ; the required information may be obtained by taking dental radiograms (see p. 321). Suppuration at the root may exist when the tooth looks perfectly healthy, does not cause pain, and is not tender on percussion. The affected tooth should be extracted, and cultivations made from the apical abscess so as to prepare an autogenous vaccine. Apical abscesses are sometimes sterile. In severe pyorrhœa alveolaris the teeth should be extracted, but in milder cases improvement often takes place with less radical treatment. When the discharge of pus is free the danger is not so great as when it is pent up behind obstruction. Tonsils, adenoids, and the other possible sources of infection already mentioned should be attended to, and vaccines may be used. If no foci are found, suspicion often falls on the alimentary canal, particularly the colon, and vaccines prepared from organisms, usually *streptococci*, found in the fæces, have often been used. The test of a vaccine is its power to produce a focal reaction in the joints, and it should be continued for a year or longer until an injection produces no more pain in the joints (Beddard). Colonic lavage and intestinal antiseptics, such as salol, bismuth salicylate and β -naphthol, have been used, especially if there is diarrhœa. Another line of treatment is the so-called "protein shock therapy," in which intravenous injections of some foreign protein are used, for instance, 50 to 100 millions of a coli or typhoid vaccine or 10 c.c. of a 10 per cent. solution of Witte's peptone in water. The joints become swollen and painful, and subsequently there is improvement. This method may be used if no primary focus can be found. Intra-muscular injections of sulphur compounds are also given. Injections of gold preparations (allochrysin, solganol) in doses of 0.01 to 0.05 gram every few days, administered in a number of courses, have recently been tried with some success. Erythema, urticaria, and even exfoliative dermatitis may result from poisoning, also nephritis, stomatitis and diarrhœa and vomiting.

Apart from specific treatment directed towards the cure of the disease, there are certain general measures and local measures of a palliative kind that must be considered. When the nutrition is poor the diet should not be stinted ; on the other hand when the nutrition is good a low calorie diet is sometimes of advantage (3) and a low purine may also be valuable, especially when the blood uric acid is high. Successful results have been obtained from liver treatment (8). A moderate use of alcoholic drinks may be allowed. The patient should be well clothed in flannel, a warm dry atmosphere should be looked for, and changes of temperature avoided. Various health resorts and spas fulfilling these requirements have been found beneficial, such as Buxton, Bath, Harrogate, and Strathpeffer, at home, and Aix-les-Bains, Aix-la-Chapelle, Baden-Baden, and Wiesbaden, abroad. Internally arsenic in full doses, aspirin, sodium salicylate, guaiacol, iodide of iron, and vitamins A and D are most valuable, and they must be continued, with such intermissions as may be desirable, for weeks or months. Thyroid extract has also given good results. The joints themselves should be kept at rest in splints during the active stage of the disease ; tincture of iodine may be applied.

After pain has subsided massage and passive and active movements will help to restore the mobility of the joints and the muscular nutrition; it is a good plan to apply heat to the joint before massage is carried out, as the mobility is increased by the vaso-dilatation. In fact, cures have been related after removing surgically the ganglia of the cervical or lumbar sympathetic as in the treatment of Raynaud's disease (6). Histamine injections may also help (7). Peat baths, mud baths, electric light baths, hot air baths and hot water baths, including the whirlpool bath, may be used. Electricity may be given in the form of diathermy, the continuous galvanic current, high frequency, and ionisation with salicylic ions. Sometimes it is found impossible to get a freely movable joint, and then ankylosis in the most useful position should be aimed at.

GOUT

This name is given to a form of arthritis associated with an increase of uric acid in the blood and a deposit of crystalline sodium biurate in the joints and other tissues. In the majority of cases the feet, and especially the great toe joints, are first attacked, whence the classical name *podagra*; but the joints of the hand (*chiragra*) and other articulations are subsequently, and much less commonly, affected first.

Ætiology. Gout is well known to be strongly hereditary, so that the descendants of a gouty stock are liable to outbreaks of the disorder at an early age and with comparatively little exciting cause. It is more common in men than in women, and is a disease of middle life or advanced age, though it does occasionally, in the hereditary cases just referred to, appear as early as the age of twenty; and it has been seen in boys who were only eight, nine, or twelve years old. It has been regarded as a disease of the rich, from which the poor escape; but this is not true, as the disease is often seen in its most typical form among hospital patients and others in poor circumstances. The influence of wealth is related to diet, which is the most important ætiological factor; and the ingestion of large quantities of food, especially those kinds which are rich in purin bodies, with abundance of alcoholic liquors, directly contributes to that condition of the blood and tissues which is the essence of gout. Of alcoholic beverages, malt liquors and the stronger wines, like port and sherry, seem to be more prejudicial than distilled spirits. The effects of dietetic excess are aggravated by a sedentary life; and, as a rule, an occupation is prejudicial in proportion as it tempts to one or necessitates the other. Sepsis, especially dental sepsis, predisposes to gout, as do also those occupations which expose the operatives to lead intoxication (see p. 587). In those who are predisposed to it, or who have already had manifestations, an attack may be brought on by an aggravation of the dietetic excesses, or by any departure from the strictest regularity hitherto found necessary, by anxiety and mental worry. Gout attacks more readily an injured joint and it is supposed that pressure of the boot on the metatarso-phalangeal joint of the big toe makes that joint so liable to attack.

Morbid Anatomy. The joint changes in chronic gout are usually but by no means invariably of the osteoarthritic type. The pathological changes are similar, therefore, to those already described with the important addition of deposits of sodium biurate in the constituent elements of the joint. In addition to uratic deposits in the articular cartilage, synovial membrane and capsule and in periarticular structures, collections of the crystals of sodium biurate often occur occupying cystic spaces or "punched-out" areas in the subarticular cancellous tissue; they also take place on the surface of the bones, where they are partly surrounded by osteophytes or sharp projecting spurs from the bones. In bursæ, in tendon sheaths, in the cartilage of the ear, or in the skin of parts not immediately over the joints, the essential change is also the accumulation of biurate crystals. Exceptionally, true gouty deposit has been found in other

situations—*e.g.* on the spinal meninges, and on the meninges of the cerebellum. Arteriosclerosis and primary contracted kidney are often present in gout.

Chemical Pathology. The uric acid of the urine is derived from two sources: (1) From the purin bodies in the food (*exogenous*). These substances (xanthin, hypoxanthin, etc.) are contained in tea, coffee, cocoa, in the nuclei of all cells, and so they are present in meat, sweetbreads and other cellular organs. The purins derived from this source are not altogether excreted as uric acid in the urine. A large amount is destroyed in the body. Still it is possible to raise very considerably the amount of urates in the urine by partaking largely of such rich foods. (2) From the wear and tear of the tissue cells of the body (*endogenous*). If a man takes a purin-free diet, *i.e.* lives on bread, vegetables, milk products and eggs, the uric acid in the urine is purely endogenous; and as this remains constant in amount for an indefinite period on a diet of this kind, it shows that the body has the power of synthesising purins. Histidin and arginin may be one source (Hopkins and Ackroyd). It has also been found that the endogenous uric acid falls to about a half on an almost protein-free diet (1), and also on a carbohydrate-free diet (2); but in the latter case the blood uric acid rises and an attack of gout may be precipitated.
